Abstract

Research on leverage and asset prices emphasizes the direct effect of bank lending enabling excessive risk-taking by financially-constrained agents. Studies implicitly focus on a special setting whereby agents are myopic and fail to anticipate cheaper loans and higher asset prices resulting from credit booms. Using China’s staggered liberalization of stock-margin lending from 2010-2015—which resulted in a bank/brokerage-credit-fueled stock-market bubble—we show, to the contrary, that unconstrained investors speculated on likely-to-qualify-for-lending stocks, amplified volatility and increased constrained-household fragility. The parallel-trends criterion underlying empirics is unnecessarily restrictive. Policy implications differ in general non-myopic settings, including in housing markets.

1 Introduction

An important macro-finance literature associates credit cycles with asset price boom-bust patterns—typically using panel regressions that exploit cross-country (see, e.g., Borio & Lowe, 2002; Schularick & Taylor, 2012) or cross-county variation (see, e.g., Mian & Sufi (2009)). Prominent historical examples include the rise of margin lending in the U.S. stock market preceding the Great Depression (Galbraith, 2009) and the growth of loan-to-value ratios in the U.S. housing market preceding the Great Recession of 2008. This literature has understandably attracted considerable interest from central bankers and other financial market regulators.

Theories addressing these empirical patterns emphasize a “direct” effect: an expansion of bank lending to financially constrained households generating higher asset prices and financial fragility through a variety of mechanisms. A non-exhaustive list includes (1) complacent or neglectful creditors underestimating downside or tail risk (Minsky, 1977; Gennaioli et al., 2012); (2) reckless lending in the form of lax screening of naive investors (Dell’Ariccia & Marquez, 2006; Keys et al., 2012); (3) leverage constraints (Geanakoplos, 2010); and (4) intermediary frictions or balance sheets (Bernanke & Gertler, 1989; Kiyotaki & Moore, 1997; Adrian & Shin, 2010; Brunnermeier & Sannikov, 2014). A key element of all such narratives is the notion that new buying by previously constrained households is responsible for price movements.

Following these theories, empirical work studying the causal effect of credit supply on asset prices generally utilizes deregulatory changes that increase credit supply for some group (treatment) and not others (control) (see, e.g., Favara & Imbs, 2015; Di Maggio & Kermani, 2017). To identify a direct effect, these studies rely on a parallel-trends assumption, that is, that asset prices for the treated and control groups trend similarly before the deregulatory event date. Policy work, in turn, focuses on the right level of leverage regulation to attenuate these direct effects.

Our paper points out that direct effects are only half the story. Theoretically, if the direct credit-supply effect is large—as is the premise of existing theoretical and empirical work—then anticipatory speculation becomes ex-ante profitable. In the context of stock markets, speculation or front-running by unconstrained and sophisticated investors such as hedge funds and mutual funds can lead to overshooting and greatly magnify asset price movements (De Long et al., 1990; Lakonishok et al., 1992; Hong & Stein, 1999; Abreu & Brunnermeier, 2003; Stein, 2009). Existing empirical research has at least anecdotally implicated unconstrained investors in riding booms such as the Internet Bubble of the late 1990s (Brunnermeier & Nagel, 2004; Griffin et al., 2011) or the South Sea Bubble two centuries before (Temen & Voth, 2004). In housing...
markets, all agents, be they first time home buyers or investors, may optimally time purchases in anticipation of a boom (see, e.g., Glaeser et al., 2008; Haughwout et al., 2011; Choi et al., 2016; DeFusco et al., 2017). Indeed, relatively high-income/high credit score borrowers, as well as investors, participated in the wave of new loans that preceded the Great Recession of 2008 (e.g. Adelino et al., 2016; Albanesi et al., 2017).

However, by requiring parallel trends, empirical studies implicitly focus on a special setting in which agents are “myopic” and fail to anticipate cheaper loans and higher prices resulting from credit booms. In general, this criterion is unnecessarily restrictive and will only hold in particular contexts where (1) no agents are able to time their purchases; (2) agents are explicitly myopic; (3) there are substantial frictions to arbitrage, or (4) deregulatory events (credit supply shifts) are entirely unpredictable. While necessary for implementing standard difference-in-difference designs, requiring the parallel trends criterion eliminates the possibility of studying the rich and economically meaningful patterns generated by speculation. We often expect asset prices to rise in anticipation of credit supply shocks and hence should focus on identification criteria that are valid in general non-myopic settings.

This is particularly the case because extrapolating from myopic settings or studies is problematic from a policy perspective. Anticipatory speculation may generate excess price volatility and lead constrained households to buy assets at higher prices relative to a myopic world. If the dangers of credit booms stem from speculation in anticipation of credit—rather than the extension of new credit per se—then estimates of the costs and benefits of macro-prudential regulations on leverage or credit will be biased. Furthermore, in contexts where anticipation contributes to credit-booms gone wrong, anti-speculative measures may be productively included in the macro-prudential policy toolkit.

We propose measuring three distinct empirical objects related to credit expansions: (i) anticipatory effects, or ex-ante changes in asset prices in the lead up to a credit boom, (ii) direct effects, the ex-post changes in asset prices that would occur in the absence of anticipation, and (iii) overshooting, or the degree to which ex-ante speculation causes ex-post asset prices to exceed the level implied by the direct effect.

We utilize the recent credit cycle in China as an example of a non-myopic setting to demonstrate the implications of this proposal for methodology and policy. From 2010 to 2015 the Chinese stock market received a large credit supply shock as a result of a government liberalization of margin lending. In contrast to margin deregulations in other countries, the Chinese government actively encouraged government-owned banks and brokerage firms to lend to households for stock purchases. As a result, there was a historically rapid expansion of margin debt, peaking at 3.5% of GDP and 4% of market capitalization (see Figure 1). At the peak, nearly 2 trillion yuan of margin loans were supplied to Chinese households. Since China has stringent short-sales constraints, speculation and credit gave rise to a bubble (Scheinkman & Xiong (2003), Geanakoplos (2010)), which subsequently gave way to a crash and government bailouts. In other words,
the Chinese stock market had a credit-fueled speculative stock market bubble that—given the lack of corresponding productivity increases in China during this period—is suggestive of the “direct” effects narrative found in the literature.

While our points apply generally to all asset markets—including housing, as we demonstrate below—the Chinese experience provides a particularly clean context in which to study the impacts of credit supply. This is because the government staggered the deregulation over a series of different vintages, including a new cohort of stocks in the margin lending liberalization at five distinct points between 2011 and 2014. The partial and gradual nature of the deregulation enables us to measure direct effects using a difference-in-difference approach—comparing marginable stocks to not-yet or never marginable stocks before and after deregulation.

Additionally, for the last three of these five vintages, the government committed to a formal rule for screening and ranking: new stocks qualified for margin lending according to a published formula based on publicly available information on market capitalization and trading volume. This allows us to characterize the ex-ante information on the coming credit expansion that was available to sophisticated, unconstrained investors. This feature provides a unique opportunity to identify anticipation: we are able to test whether ex-ante information leads to staggered advance increases in asset prices—mirroring the staggered nature of the liberalization.\(^2\)

We begin our analysis by presenting several pieces of evidence showing unconstrained institutional investors speculating on the timing of the margin lending roll-out. In the absence of anticipation, we would expect price and trading effects to begin only when or after margin becomes available. Alternatively, with anticipation effects, we expect prices and trading—i.e. buying by unconstrained investors—to rise in advance of new credit supply (but after regulators make their intentions public). These increases need not be instantaneous, and should be gradual to the extent that unconstrained investors have holding costs or uncertainty regarding the likelihood or form of deregulation. Our findings, summarized in Figures 3–4, show that (i) asset prices, (ii) purchases by large investors and mutual funds, and (iii) turnover all rise for affected stocks in the months preceding the roll-out of each vintage.\(^3\)

To capture these patterns, we propose and implement a non-myopic difference-in-difference estimator to test for anticipation and appropriately measure (net) ex-post effects. Our approach allows for differential ex-ante effects amongst soon-to-be-marginable stocks, enabling us to both account for attenuation due to pre-trends and explicitly quantify the role of anticipation. Consistent with the aforementioned figures, we

\(^2\)In other settings, this timing information is missing and studies typically use a short window with which to verify the parallel-trends assumption. Such an arbitrarily short window might miss anticipation effects to the extent prices of treated and control groups already converged.

\(^3\)In all figures, vertical lines display the start date of each of the three vintages for which the criteria for a stocks inclusion was published ex-ante.
find strong evidence of anticipation: valuations among soon-to-be-marginable stocks grow differentially just before deregulation. With this strategy, we estimate an overall ex-post effect suggesting a 57-cent increase in market capitalization per dollar of margin debt. This is substantially higher than myopic estimates would predict. Extensive placebo tests rule out reverse causality or spurious correlation concerns. We also show that indirect effects—spillover of the introduction of margin lending onto never marginable stocks via wealth or substitution effects—which might downward bias our findings, are small.

In the presence of anticipation, theory suggests that a stock’s valuation at the moment of deregulation will incorporate any direct effect, but will also be influenced by the extent to which anticipatory speculators misestimate. For example, if unconstrained investors overestimate the direct effect of margin lending on stock prices. In such a case, our estimates—that a dollar of margin debt leads to an overall increase of 57 cents in market capitalization—will actually be the average of two distinct effects of interest: (i) the direct effect of margin debt on market cap, and (ii) overshooting due to anticipation.

To this end, we develop an empirical strategy to test for the presence of overshooting, and to separate these two channels. We utilize the fact that anticipatory increases in valuations are concentrated in those most likely to become marginable (“high-ranked” according to the publicly disclosed formula as opposed to “low-ranked” stocks that barely ended up on the marginable list). Accordingly, we hypothesize that—if anticipation led to overshooting—ex-post valuations should be highest for those highly-ranked stocks. To evaluate this, we develop and implement an expanded, triple-difference version of our non-myopic strategy. Our conservative estimates using this approach suggest that anticipation is responsible for at least 50 percent of the ex-post effect, while the remaining 50 percent is due to the direct effect of margin debt.

We further exploit the difference between high-ranked and low-ranked stocks to examine the policy implications of anticipation effects. To do so, we use a random sample margin trading accounts from a brokerage house to develop measures of leverage at the account level. We show that leverage of households owning “high-ranked” stocks are comparable to those owning “low-ranked” stocks. Given our earlier results on price overshooting for “high-ranked” stocks, this indicates an increase in financial fragility driven by anticipation: since overshooting increases volatility—but leverage is the same—the distance to default is lower for these households. Moreover, we additionally provide evidence for anticipation of the introduction of shadow margin lending at the end of 2014, which contributed to the subsequent crash of the Chinese stock market (Bian et al., 2017a,b).

Finally, we show that anticipation plays an underappreciated role in the housing-credit supply literature. Investment home purchases by unconstrained agents are naturally analogous to speculation in stock mar-

---

4 Around 2 percent of our sample of brokerage accounts had margin accounts during our sample period, and they typically owned only a few stocks at any given point in time.
kets. However, financially constrained households may also choose to time their purchases in anticipation of cheap loans. As we point out in Section 6, both have non-trivial consequences. We apply these ideas to reinterpret evidence from both 2002-2008 subprime credit cycle and the deregulatory setting of staggered US branch banking deregulation index created by Rice & Strahan (2010) and used in Favara & Imbs (2015). We conclude that the parallel-trends criterion is a knife-edge case for housing markets as well as stock markets.

Our paper proceeds as follows. In Section 2, we provide the background to our empirical design and describe our data. In Section 3, we develop our methodology. In Section 4, we present our results. We work out the policy implications of our analysis in Section 5. We highlight the importance of anticipation effects in housing markets in Section 6. We conclude in Section 7.

2 Background and Data

2.1 China’s staggered deregulation of margin lending

Chinese regulators began experimenting with margin lending on February 13th, 2010. As a pilot program, an initial set of 90 stocks (which we refer to as Vintage 0) were opened to margin lending. The stocks selected for this initial vintage were simply those included in the two major stock market indices: the Shanghai 50 Index (50 stocks) and the Shenzhen Component index (40 stocks). Investors with at least 500,000 RMB of assets in their stock brokerage account and six months or more of trading experience qualified for margin—provided by their brokerage firms—to buy these stocks.

Effective on November 25th, 2011, the Chinese government formally began the margin lending program, extending the list of marginable stocks based on membership in two broader market indices. The extended list included 278 stocks: 180 from the Shanghai 180 Index and 98 from the Shenzhen 100 Index. We refer to the set of new stocks added at this point as Vintage 1. Furthermore, official regulations released at the start of Vintage 1 explicitly stated that the list of marginable stocks would be extended in a staggered manner.\(^5\)

For the later extensions (Vintages 2-4), the regulatory agency adopted a screening-and-ranking rule to determine which stocks would be included in each vintage. This procedure had two steps: (i) Screening out stocks that did not satisfy several criteria to rule out particularly small, volatile, illiquid, and newly listed stocks—the so called Article 24 for Shanghai and Rule 3.2 for Shenzhen;\(^6\) (ii) Ranking the remaining

---

\(^5\)See Article 28 in the Rule released by the Shanghai Stock Exchanges.

\(^6\)The criteria for both exchanges are the same: they require that stocks: (1) have been traded for more than three months; (2) have either more than 100 million tradable shares or a market value of tradable shares over 500 million; (3) have more than 4,000 shareholders; (4) have not experienced any of the following in the previous three months: (a) daily turnover less than 20% of the turnover rate of the market index; (b) the average of the absolute value price changes more than 4% off of the market index; (c) market volatility higher than the market volatility by 500%; (5) have completed the share reform; (6) are not specially treated stocks; and (7) other conditions. The official document from exchanges does not specify what the other conditions refer to. See rules on stock trading with margin loans on each stock exchange’s website.
stocks according to the formula described in Equation (1) and selecting the top 100 as candidates for the
next vintage (with some discretion). As shown in Equation (1), the ranking is based on a value-weighted
average of a stock’s size and trading volume within the exchange. The ranking procedure was conducted
by the Shanghai (SH) and Shenzhen (SZ) Stock Exchanges separately.

\[
\text{Ranking}_i = 2 \times \frac{\text{Average Tradable Market Value of Stock } i}{\text{Average Tradable Market Value of All Stocks in SH/SZ}} + \frac{\text{Average Trading Volume in yuan of Stock } i}{\text{Average Trading Volume in yuan of All Stocks in SH/SZ}}
\]  

(1)

Vintages 2-4 were opened to margin lending on January 25th, 2013 (Vintage 2), September 6th, 2013
(Vintage 3), and September 12th, 2014 (Vintage 4). Each time, approximately 100 stocks from each of the
two exchanges become newly marginable (Although there were 120 stocks from the Shanghai exchange
included in Vintage 2). After all five of these vintages, there were approximately 900 stocks in total that
could be bought on margin across the two exchanges. Table 1 summarizes the timeline of deregulation and
the number of newly marginable stocks for each extension.

According to the regulator’s public statements, the ranking procedure was based on market data over a
period before the start date of each vintage. As both the data used for the screening-and-ranking procedure
and the procedure itself are public, we were able to replicate the procedure for each extension on each
exchange using ex-ante data; we discuss this exercise in Internet Appendix A. Crucially, unconstrained
investors might plausibly be able to use these same guidelines starting at the end of 2011 to forecast the roll-
out of margin lending in real time. While the stocks included in Vintages 0 and 1 were potentially difficult
to forecast, Vintages 2, 3 and 4 could in principle be predicted fairly easily.

2.2 Margin lending and the bubble-crash episode of 2010-2015

Following the official announcement of margin deregulation at the end of 2011, margin lending in China
expanded dramatically. In Panel A of Figure 1 we plot the ratio of margin debt to market capitalization and
total market capitalization. This ratio increased from 0.5% around the end of 2012 to 4.5% in June 2015. In
yuan terms, total margin debt increased from a negligible amount at the beginning of 2012 to almost two
trillion yuan in 2015.

Coincident with the high level and rapid growth of margin debt, the Chinese stock market experienced

Footnotes:
7 These are the announcement dates of the marginable stock list. The corresponding implementation dates are January 31st, 2013
(Vintage 2), September 16th 2013 (Vintage 3), and September 22th 2014 (Vintage 4). For the purposes of our analysis, which is at the
monthly level, there is no distinction between announcement and implementation.
8 The concrete number of newly marginable stocks in each extension may be slightly more than 100, as occasionally a few marginable
stocks become non-marginable for not satisfying the screening rule.
an enormous boom. As also shown in Panel A of Figure 1, total market capitalization increased from 20 trillion yuan in mid-2014 to over 50 trillion at its peak in June 2015. It then collapsed by more than 20% within two weeks. Over the same period, the Shanghai Composite index rose from about 2000 in mid-2014 to a peak of 5166 on June 12, 2015. Subsequently, the market crashed to 3709 within three weeks.

2.3 Data and variable construction

We use stock price, trading, and financial information from CSMAR, excluding stocks on the Growth Enterprise Board (GEB). Formal margin debt balance is released by the Shanghai and Shenzhen stock exchanges on a daily basis. Our sample is from March 2009, one year before margin lending began, to October 2015. The pre-crash period is from March 2009 to May 2015. Our analysis is primarily at the monthly level.

The key independent variable of interest in our paper is Margin Debt$_{i,t}$, which refers to the yuan balance of margin borrowing for stock $i$ at the end of month $t$. Our primary outcome variable, Market Cap$_{i,t}$, is the market value of stock $i$’s tradable shares. We also consider Turnover$_{i,t}$, the number of shares traded over month $t$ scaled by the number of floating shares in the Shanghai or Shenzhen stock exchange. As a control, we sort stocks into deciles based on the past year’s book equity value; we denote decile dummies as $BE_{i,t}$.

A crucial piece of our analysis regarding anticipation effects concerns the trading behavior of unconstrained investors. While the margin lending deregulation targeted households facing financial constraints, there are many institutional investors in China who do not face such constraints. These include insurance companies and mutual funds. We rely on two datasets to get at these investors’ trading behavior. The first is an analog of the 13-F quarterly institutional ownership filings in US markets used in studies of trading by institutional investors. While data on institutional ownership in China is not quite as high quality as in the US, public companies in China do have to disclose the largest ten shareholders and their ownership in quarterly financial reports. The majority of top 10 shareholders are institutions such as insurance companies, brokerages, and occasionally mutual funds. While not a perfect measure, this variable is likely to be highly correlated with institutional ownership in a stock, reflecting the holdings of relatively unconstrained investors with lots of capital. For our analysis, we sum total ownership across the top 10 holders of floating shares and label it as the Top 10 Investors Ownership Share.

Our second measure of the holdings of unconstrained investors is based on mutual fund data from CSMAR. In China, mutual funds are required to report their stock holdings on a quarterly basis. For each stock, we calculate a Mutual Fund Ownership Share, which is the fraction of floating shares held by all mutual funds.
3 Methodology

The literature on credit booms posits a direct effect: credit supply (e.g. new margin loans) to financially-constrained households enables them to bid up prices, leading to higher valuations. In a myopic context, identifying the direct effect of a credit-supply shock is straightforward and well understood. Given some deregulatory change to a treatment group, researchers must simply validate the parallel trends assumption between this group and some control group. Doing so confirms that there are no compromising anticipatory pre-trends, and suggests that the two groups would trend similarly in the absence of deregulation.

The intuition behind this standard estimation is captured by the red line in Figure 2. The y-axis of this figure displays a treated asset’s price, while the vertical line on the x-axis denotes the relevant event date (e.g. deregulation). In a myopic world, prices will be flat before the event date and then jump discretely to a higher price after the event. The difference in the two prices represents the direct effect. In our context, this would correspond to an increase in price at the moment a stock qualifies for margin lending, driven by buying by previously constrained households.

However, we should not typically expect the pattern displayed by the red line—or, more flexibly, the parallel trends assumption—to hold. If unconstrained speculators anticipate that retail investors will get access to leverage and that prices will rise as a result, it is optimal for them to buy in advance. The anticipatory effect is positive: unconstrained investors or arbitrageurs will optimally start buying stocks that they view as likely to qualify for margin lending in advance of the margin lending deregulation, rather than substituting away from the stocks when credit is rolled out. Notice that their buying and hence price adjustment will be gradual, given that there is both uncertainty regarding the policy change and a cost of holding securities.

The gray and black lines in Figure 2 represent anticipation scenarios. For the grey line, prices move in advance of the event date (so parallel trends does not hold) in perfect anticipation of the direct effect. For the black line, prices again move in advance of the event date (and again parallel trends does not hold) but overshoot the direct effect. The destabilizing effects (the black line or overshooting scenario as opposed to the grey line) of institutional investors speculating on the path of prices are well-established in the literature and can arise in a variety of settings. To the extent there are enough institutions buying, they will have a price impact and lead to even higher prices or overshooting relative to a world with no such anticipatory speculation. This additional price effect or overshooting is particularly emphasized in De Long et al. (1990), Lakonishok et al. (1992) and Stein (2009).

In both cases, the pre-trends generated by anticipation pose two problems for conventional approaches. First, standard (e.g. difference-in-difference) techniques will underestimate the true average net effect of the event—which we refer to as the ex-post effect—because they compare the period after the event to an
artificially inflated pre-period. Second, because the price of the asset after the event pools the effect of credit with any under- or over-estimation by speculators, even an accurate estimate of the ex-post effect will not capture the direct effect of credit supply on asset prices. In general non-myopic settings it is necessary to account for anticipatory pre-trends. By doing so, it is possible to both appropriately estimate the ex-post effect of credit supply, and to quantify the impacts of anticipation.

Furthermore, from a naive perspective, anticipatory pre-trends might call into question the fundamental premise of the parallel trends assumption: that treatment and control groups would trend similarly in a world without deregulation. However, in the context of credit supply shocks (and most forseeable shocks in asset markets) theory predicts just such patterns: we should expect to see pre-treatment differences in groups that would counterfactually follow the same trends. Of course, this means that graphical evidence may not be as striking as in traditional difference-in-difference contexts (i.e. the jump on the event date is not as sharp): a theory then is necessary to study the richer phenomena that occur in contexts with anticipation. In what follows, we describe our empirical strategies for addressing anticipation.

3.1 OLS

We begin by specifying the simplest OLS approach one might take to capture the direct effect of margin lending on market capitalization. For stock $i$ in month $t$, we estimate:

$$IHS(\text{Market Cap}_{i,t}) = \alpha + \beta_0 IHS(\text{Margin Debt}_{i,t}) + \theta_1 \text{BE}_{i,t} + \gamma_i + \delta_t + \epsilon_{it} \quad (2)$$

where $IHS(\text{Market Cap}_{i,t})$ and $IHS(\text{Margin Debt}_{i,t})$ refer to the inverse hyperbolic sine of market cap and margin debt for stock $i$ in month $t + 1$, both in RMB. Book-equity deciles refer to dummy variables for inclusion in each decile of book equity at the month level, and $\gamma_i$ and $\delta_t$ are stock and month-year fixed effects, respectively. $\beta_0$ is expected to be positive. We are primarily interested in the economic magnitude of this coefficient, and because IHS-IHS as roughly similar to a log-log specification, we interpret the coefficient of interest $\beta_0$ as an elasticity.

Of course, $\beta_0$ as estimated from this approach is unlikely to identify the direct effect (or even the ex-post effect) for a number of reasons. First, this specification is subject to endogeneity concerns that are present even in myopic settings. For example, within a vintage, the fastest growing stocks might attract the largest share of margin debt, even in the absence of any direct effect. Second, even absent these concerns, the OLS approach will not be valid in non-myopic settings. Anticipation will cause $\text{Market Cap}_{i,t}$ to rise even while $\text{Margin Debt}_{i,t}$ is mechanically constrained to be 0, biasing any estimates.

9We use IHS rather than log as a transformation because margin debt for a stock can be zero.
3.2 First stage: Exploiting the staggered deregulation

To deal with the endogeneity concerns described above, we exploit the liberalization of stock margin lending, which allowed brokerage firms to lend large amounts to retail households. In particular, we instrument using the staggered rollout of the margin deregulation. To capture the impact of this deregulation on margin debt—effectively the first stage for the IV approaches described below—our simplest specification is:

\[
IHS(Margin\ Debt_{i,t}) = \gamma_0 + \gamma_1 Margin\ Trading\ Active_{i,t} + \lambda_1 BE_{i,t} + \eta_i + \tau_t + \nu_{it},
\]  

(3)

Here, Margin Trading Active_{i,t} is a dummy variable equal to one if margin trading is active in month \( t \) for stock \( i \), and zero otherwise. \( \eta_i \) and \( \tau_t \) are stock and month fixed effects, respectively. We refer to this as our “collapsed specification.”

We also consider a more general specification that allows for flexible effects across different vintages, which we refer to as our “full instruments specification:”

\[
IHS(Margin\ Debt_{i,t}) = \gamma_0 + \sum_{k=0}^{4} \gamma_k^{1} Margin\ Trading\ Active_{i,t} \times Vintage_{k_i} + \lambda_1 BE_{i,t} + \eta_i + \tau_t + \nu_{it}.
\]  

(4)

Here \( Vintage_{k_i} \) is an indicator equal to one if stock \( i \) is in Vintage \( k \). Thus, Margin Trading Active_{i,t} \times Vintage_{k_i} = 1 \) if margin lending is allowed in month \( t \) for stock \( i \) in Vintage \( k \) and zero otherwise.

Our first-stage regressions are similar to other studies that use deregulatory changes. The standard approach in myopic settings would directly utilize the specification in Equation (3) to instrument for \( IHS(Margin\ Debt_{i,t}) \) in a first stage, and estimate Equation (2) in a second stage. However, as doing so is not valid in the presence of anticipation, we suggest a non-myopic approach.

3.3 Difference-in-difference specifications in non-myopic settings

3.3.1 Accounting for anticipation

In order to estimate anticipatory effects, and to appropriately measure the net ex-post effects of the deregulation of margin trading in China, we consider non-myopic difference-in-difference specifications following Malani and Reif (2015). The basic notion of this approach is to use the period well before the roll-out took place as a pre-period, and to estimate separate difference-in-difference coefficients for (i) the months just before the roll-out took place (anticipatory effects), and (ii) the actual treatment period in which margin
lending was active (ex-post effects).

This strategy can be seen most clearly in the following reduced-form specification:

\[
\text{IHS(Market Cap)}_{i,t} = \alpha + \beta_0 \text{Margin Trading Active}_{i,t} + \sum_{j=1}^{S} \beta_j D_{i,t+j} + \theta_1 BE_{i,t} + \gamma_i + \delta_t + \varepsilon_{it}. \tag{5}
\]

The key to this approach is the inclusion of a series of dummies to allow differential effects for treated stocks in the period just before deregulation. These are captured by the indicators \(D_{i,t+j}\), which are equal to one if margin trading initially becomes active for stock \(i\) in period \(t + j\), and zero otherwise. Put more simply, \(D_{i,t+j}\) is variable that, for a specific stock \(i\), indicates that margin lending is about to roll-out. \(S\) captures the number of periods in advance investors might feasibly speculate upon the coming introduction of margin lending. In the stylized example shown in Figure 2, \(\beta_1, \ldots, \beta_S\) capture the upward trend preceding the event date, while \(\beta_0\) captures the difference between the average and the baseline price in the period after the event date.\(^{10}\)

Because we are explicitly interested in the impacts of margin debt, we focus primarily on an IV version of the above rather than the reduced form itself. In the first stage, we use Margin Trading Active_{i,t} as an excluded instrument for IHS(Margin Debt)_{i,t} following Equation (3).\(^{11}\) In the second stage, we estimate:

\[
\text{IHS(Market Cap)}_{i,t} = \alpha + \beta_0 \text{IHS(Margin Debt)}_{i,t} + \sum_{j=1}^{S} \beta_j D_{i,t+j} + \theta_1 BE_{i,t} + \gamma_i + \delta_t + \varepsilon_{it}. \tag{6}
\]

While market cap is the primary variable of interest, we also consider non-myopic specifications for a variety of other outcomes to support our analysis. In particular, we estimate similar specifications using the proportion of institutional ownership of stocks and turnover of those stocks as dependent variables. In all specifications, \(\beta_j > 0\) for \(j > 0\) indicates the presence of anticipatory effects: the market capitalization of soon-to-be marginable stocks grows relative to a control group in the period leading up to the roll out. Appropriately accounting for anticipation, the coefficient \(\beta_0\) captures the net ex-post effect of margin lending.

In this context, the standard approach in the literature—which we call a myopic estimate—is simply a special case in which we set for \(\beta_j = 0\) for \(j > 0\). As noted in Malani & Reif (2015), failing to account for any ex-ante changes in anticipation of the margin lending roll-out will cause a researcher to estimate the true (ex-post) effects with bias. In particular, if stock prices rise in anticipation of future margin lending, the myopic approach will underestimate the true effects. The intuition here is simple, the myopic difference-in-difference estimator compares a post-treatment price to an artificially high pre-treatment price—which has

---

\(^{10}\) i.e. the x-axis or the price level before the black and gray lines diverge from the red.

\(^{11}\) In more general settings, it would be necessary to modify the first stage itself to account for anticipation, i.e. to also include \(\sum_{j=1}^{S} \psi_j D_{i,t+j}\) in Equation 3. However, because margin debt is mechanically constrained to be 0 before deregulation in our setting, these effects are redundant.
already risen in anticipation of treatment.

### 3.3.2 Accounting for price overshooting

We next develop two strategies that provide further evidence on the presence of anticipation and allow
direct tests of overshooting. In our first and preferred specification we further interact the non-myopic
specifications above with a variable intended to capture variation in investors ability to anticipate which
stocks were about to become marginable: the likelihood of inclusion in the coming vintage.

The later vintages were determined on the basis of a well defined rule based on a stock’s ranking in
terms of volume and market value at the time of the rollout. As a result, in the months prior to the roll-out
itself, there was uncertainty over which stocks would have a sufficient ranking to qualify. We exploit cross-
sectional variation in this uncertainty by comparing—within the stocks that qualified for a given vintage—
those with the highest rankings (above median rank) to those with the lowest rankings (below median rank).

The logic underlying this approach is that, from the perspective of a speculator ex-ante, the highest rank-
ing stocks are almost certain to qualify: a large shift in the rankings would be necessary to disqualify such
a stock. Alternatively, low-ranking stocks are relatively uncertain, as a marginal change in rank might lead
to disqualification. As a result, we expect speculators to differentially focus attention on and buy the high-
est ranking stocks, generating larger anticipatory price effects in these stocks. However, because both high
and low ranking stocks are quite similar otherwise, there is no reason to expect a differential direct effect
of margin debt. Put differently: in the absence of anticipation, there is no reason a constrained household
with new access to credit would prefer high- over low-ranking stocks within a vintage. Consequently, any
difference in ex-post effects between high- and low-ranking stocks must be the result of overshooting due
to speculation.

To be explicit, in a second stage, we estimate

\[
\text{IHS(Market Cap)}_{i,t} = \alpha + \beta_0 \text{IHS(Margin Debt)}_{i,t} + \sum_{j=1}^{S} \beta_j D_{i,t+j} \\
+ \eta_0 \text{IHS(Margin Debt)}_{i,t} \times \text{High Rank}_i + \sum_{j=1}^{S} \eta_j D_{i,t+j} \times \text{High Rank}_i \\
+ \theta_1 BE_{i,t} + \gamma_i + \delta_t + \varepsilon_{it}. \tag{7}
\]

High Rank, is an indicator equal to one if a stock is above the median rank within its vintage. In a first stage,
we include Margin Trading Active, and Margin Trading Active \(\times\) High Rank, as excluded instruments
for IHS(Margin Debt), and IHS(Margin Debt) \(\times\) High Rank. These IV estimates provide coefficients that
can be interpreted as elasticities. Our approach provides a direct test of overshooting. However, there may, of course, be overshooting in both high and low ranking stocks. To the extent that this is the case, our strategy provides a lower bound on the magnitude of the overshooting effect.

We also recognize that researchers may not be able to utilize the above strategy in other contexts. Nonetheless, one can still decompose anticipation versus direct effects if one is willing to assume that overshooting effects are transitory and persists only for some period $S$ after the event date, and also that direct effects are persistent. (Note that we use $S$ here for symmetry with our pre-trend event window for notational convenience. These event windows can differ depending on the particular context.) To capture this, we develop a specification in which we separately estimate difference-in-difference coefficients for (i) the period just before the margin lending roll-out, and (ii) the entire period after the roll-out (“long-run”) while (iii) allowing for differential effects in the period immediately after the rollout. (i) Captures any anticipatory effects, (ii) captures the direct effect, and (iii) separately estimates the impact of overshooting.

Specifically, we can estimate IV versions of the specifications above, in which we explicitly estimate the elasticity of market cap with respect to margin debt in the long run period (times $t > S$). In particular, in a first stage, we allow Margin Trading Active $i,t$ to instrument for IHS(Margin Debt)$_{i,t}$

$$\text{IHS(Margin Debt)}_{i,t} = \alpha + \beta_0 \text{Margin Trading Active}_{i,t} + \sum_{j=-(S-1)}^{S} \kappa_j D_{i,t+j} + \theta_1 B E_{i,t} + \gamma_i + \delta_t + \varepsilon_{it}. \quad (8)$$

For the second stage, we estimate:

$$\text{IHS(Market Cap)}_{i,t} = \alpha + \beta_0 \text{IHS(Margin Debt)}_{i,t} + \sum_{j=-(S-1)}^{S} \kappa_j D_{i,t+j} + \theta_1 B E_{i,t} + \gamma_i + \delta_t + \varepsilon_{it}. \quad (9)$$

We prefer our first strategy. While we have a sense of what the pre-trend event window $S$ is given our institutional context, we do not have the same confidence on how long it might take the overshooting to mean revert. As such picking an $S$ for our post-event overshooting window becomes more challenging.

### 3.4 What about indirect effects?

Our approach implicitly assumes that there are not large spillovers: indirect effects from the introduction of margin lending for treated stocks onto the control group of untreated stocks. Indirect effects might occur, for example, if households use margin on one set of stocks to free up equity to buy another set of stocks. Alternatively, households might substitute away from the higher priced marginable stocks to lower priced non-marginable stocks. As we demonstrate in Section 5.2, such a no-spillover assumptions is reasonable in China, perhaps because most retail investors hold only a handful of their favorite speculative stocks, typi-
cally in the same size category. Moreover, to the extent that indirect effects exist, this would only downward bias our measure of the direct effect, which we find to be economically significant.

4 Empirical Results

4.1 OLS Estimates

The results from our OLS specifications are shown in Table 2. The coefficients of $IHS(Margin\ Debt_{i,t})$, which we interpret as elasticities, are all positive and statistically significant. In column (1) where there are no controls, the coefficient of margin debt is significantly positive at 0.081. In column (2) where we add book-equity decile dummies and industry fixed effects, the coefficient is 0.038. In column (3) where we add book-equity and time effects, the coefficient is 0.025.

Our most conservative specification includes both time and stock fixed effects. Even for this conservative specification, there is a precisely measured positive effect. As shown in Column (4), the estimated elasticity is 0.005. Given the relative scales of market cap and margin debt in this context (margin debt is nearly two orders of magnitude smaller than market cap), even this conservative estimate is economically sizable. Evaluated at the means of both variables, this coefficient suggests that a one dollar increase in margin debt corresponds to roughly a 40 cents increase in stock valuation. A useful comparison is the case of perfect pass through, in which a one dollar increase in margin debt would correspondingly increase market cap by one dollar.

4.2 First-stage estimates

Panel B of Figure 1 displays the staggered rollout of stock margin lending by vintages. It is easy to see from this figure that the staggered deregulation events will be powerful instruments for margin debt. In Table 3, we display results from the corresponding first stage regressions described in Equations (3) and (4). The column labeled collapsed, corresponding to Equation (3), shows that there is a strong, positive, and statistically significant impact of the margin lending rollout on margin debt itself, with a coefficient of just over 19. The column labeled full, corresponding to Equation (4), shows that these effects are relatively constant across the five vintages, if marginally smaller in earlier vintages.

12 Average market cap over our sample period is 80.8 times the size of average margin debt.
4.3 Non-myopic IV estimates

As Figure 3 makes clear, the assumption of no anticipatory effects appears to be untrue in the context of the deregulation of margin lending in China. The figure, which plots the inverse hyperbolic sine of market cap—after netting out stock, month, and book-equity decile fixed effects—displays evidence of sharp rises in market cap for Vintages 2, 3 and 4 in anticipation of the introduction of margin trading for those stocks. In this figure—and many that follow—we omit Vintages 0 and 1 in order to keep the graphs clear and avoid over-cluttering. As discussed elsewhere, these vintages were difficult to predict and hence (as expected and shown in Table A.II) displayed minimal evidence of anticipation.

There are evident pre-trends for the treated groups in the pre-treatment periods. While in other settings, it might be difficult to attribute these pre-trends to anticipation—they might, for example, reflect the endogeneity of treatment itself—we believe the staggered nature of the roll-out provides strong support of anticipation. Replicating the roll-out, the increases in market cap are themselves staggered, with the rises for each vintage just preceding deregulation for that vintage.

Table 4 presents both reduced form and IV evidence from non-myopic specifications intended to capture the patterns presented in Figure 3. In the reduced form specification given in the caption, the net effect of margin lending is captured by the coefficient labeled Ex-Post Effect. The coefficients labeled IHS(Margin Debt) in our IV specifications can be explicitly interpreted as elasticities of market capitalization with respect to margin debt. As a baseline, the third and sixth columns, labeled Myopic, report the myopic reduced form and IV specifications described in the table caption where we deliberately and erroneously assume there are no anticipation effects. The remaining columns account for anticipation: the first and fourth columns allow for six months of anticipation, while the second and fifth columns allow for six quarters of anticipation.

First, these estimates provide strong evidence of the existence of anticipatory effects, as evidenced by the positive and significant coefficients labeled as ex-ante effects in these tables. Market cap grows significantly in soon-to-be-marginable stocks in the months or quarters just prior to the margin lending roll-out, when compared with stocks that are not marginable.

Additionally, these estimates show that failing to account for anticipation substantially attenuates the net impact of margin lending on market cap. When accounting for six months of anticipatory effects, the estimated reduced form coefficient rises from 0.065 to 0.127, and further to 0.214 when accounting for six quarters of anticipation. The IV estimates, which provide more economically interpretable coefficients, suggest that the elasticity grows from 0.003 with no anticipation, to 0.007 or 0.011 with six months or six quarters. Evaluated at the averages, our six month estimates suggest that—accounting for anticipation—an additional dollar of margin debt leads to a 57 cent increase in market cap, compared to 24 cents in our
4.4 Further evidence from unconstrained-investor holdings and trades

To confirm that the results above are driven by anticipation, we next directly examine the behavior of two groups of investors we expect to be relatively unconstrained even prior to the introduction of margin lending. Specifically, we examine the behavior of mutual funds, and of the largest holders of each stock—defined as the top ten investors by quantity of shares at the stock-quarter level.

There is strong evidence that these unconstrained investors increased their holdings in anticipation of the roll-out of margin lending. Figure 5 displays the patterns of ownership by both mutual funds and the top 10 investors over our sample period for Vintages 2, 3 and 4. We also include the shares held in never marginable stocks, as a comparison group. The two panels plot residuals of the share of ownership by mutual funds and the top 10 investors, respectively, after netting out stock, quarter, and book equity decile fixed effects. For all three vintages, there is graphical evidence that these relatively unconstrained investors contributed to the anticipatory rise in market cap. Relative to the never marginable group, the share of ownership for these unconstrained investors rose in the months prior to the roll-out date of the vintage (and much farther in advance for Vintage 2). Perhaps the most pronounced evidence comes from Vintage 4, which shows a steep increase in both groups in relatively close proximity to the roll-out.

Table 5 displays regression results corresponding to Figure 5, but, to be conservative, including stocks in all vintages. The specifications are identical to those in Equation (5), but replace the dependent variable with the share of ownership by unconstrained investors (defined as either mutual funds or the top 10 investors). They are estimated at the quarterly level, corresponding to the frequency of our data on these investors. In our non-myopic specifications we show two quarters of ex-ante effects to match the 6 months shown in our specifications that utilize monthly data.

The first two columns of this table present results for mutual funds. As a baseline, the column labeled Myopic shows results from a myopic difference-in-difference specification that does not account for anticipation. Ignoring anticipation, it appears that there is a marginally significant negative effect of the margin lending rollout on mutual fund holdings. However, the column labeled Quarterly Lags shows that this negative effect is largely an artifact of anticipation. Allowing for two quarters of anticipation, the negative effect drops and becomes insignificant.

Perhaps more importantly, there are statistically significant positive coefficients representing ex-ante effects in each of the two quarters preceding the margin lending roll-out. These coefficients suggest that by the quarter just prior to the roll-out, mutual fund holdings increased by 0.7 percentage points on average—
or 41 percent—relative to never marginable stocks. The top 10 investors show a similar pattern: a negative (although insignificant) coefficient in the myopic specification, which is attenuated when allowing for anticipation. Again, there are positive and statistically significant ex-ante effects for the top 10 investors in the quarters just before the roll-out. These estimates suggest that these investors had increased their holdings in soon to be marginable stocks by 3.6 percentage points, or 7.8 percent, in last quarter before margin lending began.

We also examine whether there is visible evidence of anticipation in turnover for the stocks that qualified for margin lending. Figure 4 shows residualized turnover for Vintages 2, 3 and 4, as well as for never marginable stocks, over our sample period. Within each group, this figure plots average turnover after netting out month, stock, and book-equity decile fixed effects. The plot shows sharp increases in turnover for each of the vintages just prior to the margin lending rollout, particularly for Vintages 2 and 3. For all three vintages, these spikes recede fairly quickly following the roll-out.

The final two columns of Table 5 display regression results corresponding to these figures. We once again estimate a version of Equation 5 at the monthly level, but replace the dependent variable with our measure of turnover. There are significant increases in turnover relative to the never marginable group both ex-ante, in the two quarters preceding the roll-out, and after the rollout. The effect on turnover in the quarter before the roll-out, at 0.164, is nearly double the ex-post effect of 0.087. These anticipatory increases in turnover are directly consistent with the presence of unconstrained investors speculating in anticipation of the margin lending roll-out.

4.5 Direct effect versus price overshooting from anticipation

The elasticities estimated in Table 4 suggest that, on average, each additional dollar of margin debt leads to a 57 cent increase in market cap. However, this average potentially captures two distinct effects, the direct effect of margin debt, and the impact of overshooting due to speculation. To separate these effects, we follow the first strategy outlined in section 3.3.2, and, within each vintage, compare the stocks most likely to qualify for margin lending to those least likely to qualify.

Figure 6 displays shows the basics of this approach. Within each vintage, we plot month-stock-book equity residualized market cap, split by those above (high ranking) vs. below (low ranking) the median according to the screening and ranking formula. There are two primary takeaways from these figures. First, there is differential anticipation for high- versus low ranking stocks in the period preceding the introduction margin lending: market cap rises before the roll-out to a greater extent for high ranking stocks in all three of the predictable vintages (Vintages 2-4). This confirms our assertion that speculators are more likely to pur-
chases stocks that are almost sure to be included in the upcoming vintage. Second, this difference does not disappear once margin lending becomes active. Despite there being little fundamental difference between high and low ranking stocks, market cap for high ranking stocks remains above that of low ranking stocks for months after the roll-out. This provides direct evidence that speculation led to overshooting.

To quantify these effects, we show the results from the non-myopic triple-difference specification described in Equation 7 (as well as a reduced form version of the same specification) in Table 6.\textsuperscript{13} This table confirms both points described in the previous paragraph. As confirmed in columns, (1), (2), (4), and (5), anticipation caused high ranking stocks to have statistically significantly higher market cap in each of the 6 months or quarters preceding the introduction of margin lending. Furthermore, high ranking stocks saw a significantly larger effect ex-post. Summing the ex-post effect for low ranking stocks in column (4) (denoted by the coefficient on IHS(Margin Debt)) with the differential ex-post effect for high ranking stocks (denoted by the coefficient on IHS(Margin Debt) × High Rank), the overall elasticity for high ranking stocks is 0.014. This suggests that, for high ranking stocks, each additional dollar of margin debt led to an additional $1.13 of market cap. The differential between low and high ranking stocks suggests that, as a lower bound, 64 cents of this is due to overshooting—suggesting the direct effect is 49 cents. In other words, more than 50 percent of the net ex-post effect is due to overshooting for high ranking stocks.

4.6 Placebo tests

4.6.1 Randomizing event dates

One potential concern is that the particulars of the screening and ranking procedure itself might create mechanical effects in the set of stocks that we study, even in the absence of any speculative or direct impact of margin debt. To rule out this possibility, we perform a series of placebo exercises. In particular, we randomly select a date and define a placebo treatment group relative to that date following the screening and ranking rule. Effectively choosing the top 100 stocks on each exchange according to the published formula. We then conduct our main specifications: both the initial non-myopic difference-in-difference specification, and the triple difference that incorporates high-vs-low ranking stocks.

Table 7 displays the results from these exercises. The first five columns present versions of the non-myopic difference-in-difference approach. To avoid contaminating our placebo treatment group with actual impacts of the margin lending roll out, we took two approaches. In the first three columns, we randomly selected a date using our entire period, but considered only stocks that never qualified for margin lending in constructing our placebo group. In the second two columns, we restricted our dates to the period preceding

\textsuperscript{13}This table omits vintages 1 and 2, as those vintages were not selected using the screening and ranking rule.
the start of Vintage 2, but included stocks that qualified for Vintages 2, 3 and 4 when constructing our placebo group. Note that, because of the early start date in these last two columns, we are unable to show quarterly lags. In both cases, we see no evidence of anticipation. Furthermore, there is no evidence of a positive direct effect. In fact, there appears to be a negative ex-post effect, likely caused by regression to the mean amongst high ranking stocks.

The final three columns repeat the first three columns but implement our triple difference approach. We see no evidence of anticipation, and no evidence of a difference between high and low ranking stocks before or after the placebo date. This suggests that our findings are not driven by the procedure, and that our assertion that high and low ranking stocks are similar is reasonable.

### 4.6.2 Heterogeneity in early versus late vintages

While the stocks included in Vintages 2, 3 and 4 were included on the basis of a well defined and publicly available rule, the early vintages were chosen in a less systematic and transparent way. As a result, we expect that the marginable stocks in these vintages were more difficult to predict in advance of the rollout. To test this prediction, we estimate a triple difference version of our non-myopic specifications, incorporating the difference between early and later vintages. The results are in the Internet Appendix.

### 5 Policy Implications

#### 5.1 Speculation and fragility of financially-constrained households

We now draw some implications of anticipation effects for policy. From a regulatory perspective, the potential for overshooting generated by anticipation—and the associated increase in volatility—is a primary concern. Recalling the overshooting scenario presented in Figure 2, note that prices have already risen by the time new credit becomes available. Consequently, constrained households must buy at higher prices, and face any potential corrections that follow. If the households holding such stocks do not correspondingly adjust their leverage, they will face an increase in financial fragility.

To see if this sort of mechanism is empirically relevant, we extend our previous analysis on price overshooting for high-ranked versus low-ranked stocks in Vintages 2, 3, and 4. There, we interpreted the difference in ex-post prices as a lower bound on the causal effect of anticipatory speculation on overshooting. Because we see significant overshooting in high-ranked stocks relative to low-ranked, we next compare leverage of financially-constrained households owning high-ranked versus low-ranked stocks. Given that households in our sample typically own only a few stocks in their portfolios, this exercise gives us a view
into the impact of anticipation driven overshooting on leverage itself.

Given the increase in volatility generated by overshooting, we expect speculative anticipation to be associated with increased fragility unless we observe a significant deleveraging amongst constrained households holding high-ranked stocks. Alternatively, similar leverage ratios across households holding high and low-ranking stocks would suggest that experiencing overshooting increases fragility.

To conduct this additional analysis, we obtain account data of margin and regular trading from a nationwide discount broker in China. This brokerage house has representative geographic coverage in China, and the sample we have consists of 709,813 accounts, 18,593 of which are margin accounts. The sample period, January 2011 to December 2015, overlaps with the whole episode of deregulation in margin trading. The first margin trade appears in June 2012. For each account, we observe the records of all trades, and for each trade there is information regarding the transaction price and number of traded shares. In addition, for margin accounts, each trade record has a label indicating whether the transaction goes through the brokerage margin system.\(^\text{14}\)

Although the data do not provide snapshots of accounts’ stock holdings or cash balance, we can nonetheless calculate accounts’ leverage level with a few reasonable assumptions and the following steps. We first construct each account’s stock holdings at the end of each day by adding up all buys and sells of each stock (adjusted for stock splits). One issue here is that for accounts that started trading before 2011 we do not observe their initial stock positions. As a result, some positions appear to be negative based on our calculation. To deal with this, we set negative positions, whenever they appear, to be zero. Given that shorting is limited in China during our sample period, those negative positions are likely due to unobservable long positions that predate our sample. Furthermore, our inability to see these initial position biases down our estimate of accounts’ total portfolio value, because we miss the value of long positions an account starts to hold prior to 2011. That being said, the under-estimation should not be severe given the high turnover rate of retail investors in China. Once we have each account’s portfolio, we calculate the mark-to-market value of her stock holdings, labeled as Asset.\(^\text{14}\)

The second step is to track the balance of margin loans. Since we do not observe an account’s cash balance or repayment of margin loans, we assume a pecking order of cash over loans. In other words, a margin account will repay the outstanding loan whenever she has cash. This is reasonable given that margin loans are more costly than cash, though we acknowledge that there may be some investors who have outstanding loans and cash at the same time. This may bias down our estimate of the true value of margin loans. Our calculation is as follows: when an account places a buy order through the margin system, the value of the purchased position will be accumulated to the account’s margin loan; when the

\(^{14}\)Unfortunately, the dataset does not have any demographic information on the accounts.
account executes a sell order, whether through margin or not, the proceeds from sales will be treated as repayment to her outstanding margin borrowings (if any). In this way, we obtain each margin account’s daily balance of margin loans, denoted as Loan. The total amount of margin loans based on our data and this calculation is 1.15 billion yuan at the end of June 2015, which is approximately 0.05% of the total margin debt in the market.

Then the account leverage level (Lev) is calculated as,

$$\text{Lev} = \frac{\text{Asset}}{\text{Asset} - \text{Loan}}.$$

(10)

Note that this ratio is mark-to-market, and in order to avoid data errors we winsorize account leverage at the 99th percentile by month. Our sample mainly consists of small, retail investors. The average portfolio size over the time is 134,421 yuan, while the median is only 46,744 yuan. Also, their portfolios are under-diversified; the average investor holds only 7.4 stocks and the median is 4.6.

There is a sizable variation in the cross sectional leverage: the 95th percentile of leverage is 1.45 and the mean is 1.09. Our estimates are similar to that in Bian et al. (2017a), who use similar account data from another source. They show that the average account leverage from the formal margin channel is 1.6 (see Table 1 of their paper). The cross-sectional dispersion of leverage also increases during the booming period. For example, the 90th percentile is higher than 2 in June, while the 95th percentile reaches 3.3, at the peak. Recall that maintenance margin requirements mean that household leverage should be at maximum around 3.

We are interested in the time trend of leverage for households that own high-ranked versus low-ranked stocks. In particular, we are interested in the leverage of financially constrained households owning high-ranked versus low-ranked stocks across Vintages 2-4. To this end, in Figure 7, we plot the 95th percentile of leverage across households that own high-ranked versus low-ranked stocks in each of these vintages. We choose the 95th percentile to focus on financially-constrained households. (Many less constrained households may have a margin account that they do not use or need to buy equities). Those at the extreme are our interest as those highly levered investors are the ones who are particularly fragile during the crash period. We can see from the figures that the leverage of these financially-constrained households in high-ranked stocks are very similar to those owning low-ranked stocks. As such, we conclude that anticipatory price overshooting likely made financially-constrained households more fragile on an ex-ante basis. This would not be the case if the leverage ratios for households in high-ranked stocks were lower—which might occur if banks were unwilling to lend to households holding these stocks or if the households themselves understood the consequences.
5.2 Accounting for Indirect Effects

To account for the possibility of indirect effects, Internet Appendix Figure A.1 plots investors’ average holdings of untreated stocks—those for which formal margin was never available—around the dates when each of the last 3 vintages were opened to margin lending. For each vintage, we separately show averages for (i) investors who had holdings in some stock in the vintage at some point prior to the introduction of margin (black lines) and (ii) investors who had never held a stock in the vintage prior to the introduction (gray lines). To the extent that all households might substitute away from higher-priced marginable stocks, we would expect both lines to jump upwards leading up to and around the introduction date. To the extent that investors use margin to free up equity for untreated stocks, we would expect a differential jump after margin becomes available in the holdings of those already investing in the vintage. We see little substantial evidence of either, although there is some potentially suggestive evidence of an uptick among Vintage 2 stockholders in Panel A. Given the lack of evidence, and the fact that indirect effects would only bias our estimates toward 0, we leave further investigation of these effects to future research.

5.3 Anticipating Shadow Margin

While our focus is on formal margin lending, anticipation of non-formal “shadow” lending—which began only around the time of our vintage 4—may also have played a role in the peak of the bubble and crash in 2015. Estimates place shadow margin in 2015 at almost 1 trillion yuan—roughly half of the formal margin amount during at the peak of the bubble—and research implicates this lending in amplifying the market crash. We use data on shadow margin lending from a peer-to-peer platform that encompassed around 10% of the market during this period. We show that holdings of non-marginable stocks by unconstrained investors went up significantly going into 2015. These non-marginable stocks, which had previously underperformed, outperformed the market during this period. Unconstrained investors appear to have anticipated the rise in shadow margin lending in the Chinese stock market as well. Details on these exercises are included in the Internet Appendix.

6 Implications for Housing Markets

Given the importance of housing in the great recession, much of the recent work on credit cycles has focused on real estate markets. While our primary analysis focuses on the Chinese stock market, it is valuable to consider the relevance of anticipation in housing. In general, we expect anticipation in housing markets to be as salient as in stock markets. Mortgage credit expansions, whether driven by regulation or technology,
are unlikely to come as a complete surprise.

However, this is not to say that anticipation manifests identically in stock and real estate markets. In fact, there are potentially richer intertemporal anticipation effects in housing. The closest analog of unconstrained investors in the stock market are investment home buyers, who played a significant role in the housing bubble of 2002-2008. As financing is less of an issue, these investors should, in principle, optimally time their purchases in anticipation of buying by more financially-constrained households. That is, the scenarios laid out in Figure 2 apply to the 2002-2008 subprime credit cycle. There appears to be some evidence of such patterns in the data: for example, DeFusco et al. (2017) find that investment home volumes lead the peak of the housing bubble.

More broadly, viewing the patterns of pre-2007 lending through lens of anticipation may be constructive in integrating competing narratives of the housing crisis. A dominant view of the housing crisis, following Mian & Sufi (2009), emphasizes the expansion of credit to subprime borrowers as the key driver of the boom and subsequent crash. However, recent research, (e.g. Adelino et al., 2016; Albanesi et al., 2017), has challenged this view. These papers highlight the role of relatively high-income/high credit score borrowers, as well as investors, in the wave of new loans that preceded the recession. Anticipatory effects can nest both views. If households are non-myopic, new credit even to some segment of the distribution will change expectations and demand for all borrowers.

Importantly, such investment home buyers may not always be dominant in the housing market. There are substantial frictions in housing markets that may prevent effective speculation. However, even in the absence of speculation, constrained agents—for example first-time buyers—may change their behavior in anticipation of a credit supply shock. While expected price increases might induce investors to buy earlier, anticipation of cheaper credit, combined with frictions in refinancing, might cause some to delay their purchases until credit becomes available. Figure 8 displays an extreme version of just such a scenario. If refinancing frictions are high, and agents do not have access to cash, all individuals may delay in anticipation of cheap credit. In turn, home price growth might actually fall anticipatorily, as would occur, for instance, in the down payment model of home prices of Stein (1995). Ex-ante it is unclear which effect will dominate, but in both cases parallel trends will fail.

These points apply directly to the empirical literature on credit supply shocks. For instance, Favara & Imbs (2015) use the staggered US branch banking deregulation index created by Rice & Strahan (2010) to argue for a direct effect of credit supply on home prices. In their setting pre-trends are unmodeled and parallel trends are implicitly assumed. However, their approach ultimately combines the role of anticipation and direct effects. Much of the cross-state variation in the Rice-Strahan index occurs in the 1994-1997 period, an interim period between the announcement of deregulation and final implementation in 1997. As such, any
differences in housing prices (and new loan originations) in this period are also likely driven by speculation on the 1997 changes, rather than credit supply per-se. While these years of deregulation did not have the investment home activity that occurred between 2002-2008 subprime credit cycle, we provide suggestive evidence that anticipation effects were nonetheless important.

Figure 9 displays two figures roughly capturing some of the dynamics studied in Favara & Imbs (2015). In these figures, we divide US states into three categories based on the 1997 value of the Rice-Strahan index: low regulation (index=0), medium regulation (index between 1 and 3), and high regulation (index=4). We then display both the average house price indices across states and average growth rate of originations and within each of these groups. We display vertical lines at 1994 to indicate when “treatment” for certain states begins according to Favara & Imbs (2015), and at 1997 to display when substantial deregulation actually took place.

The primary takeaway from these figures is that in the 1994-1997 period (a “treated” period for many states from the perspective of their analysis, an anticipatory period from the perspective of the regulation), home prices in soon-to-be relatively highly regulated states grew more than in states we classify as medium or low according to the index. While less obvious, we also see a potential widening in terms of growth rates, particularly between our highly regulated and medium groups. This suggest that there was differential anticipation between these groups in the 1994-1997 period. Anticipation appears in this context in the form of delay: homeowners in states about to receive credit supply shocks may have held off on purchasing homes until that credit became available. Yet such delay creates analogous empirical issues to our setting with price overshooting: the direct effect commingles both anticipatory delay (or timing of purchases) and credit supply effects. More careful attention to separating these effects would be interesting in future studies.

7 Conclusion

In this paper, we argue that the literature on credit booms gone wrong, which has predominantly focused on the direct effect of credit supply, should simultaneously account for anticipatory effects. Our empirical exercises consider the context of the stock market and the staggered deregulation of margin lending in China that took place between 2011 and 2014. However, our points apply generally to any asset market in which agents are non-myopic, including as we show here housing markets. In non-myopic settings, parallel-trends style criterion should not, in general, be expected to hold. To identify the impact of credit expansions on asset prices in such contexts, we suggest implementing a simple non-myopic difference-in-difference estimator which decomposes ex-post effects into direct and price-overshooting effects. We also demonstrate the importance of anticipation in housing markets.

![Graph showing aggregate market cap and margin debt/market cap over time.](image)

**Panel B: Staggered Rollout of Stock Margin Lending: Margin Debt/Market Cap by Vintage**

![Graph showing staggered rollout of margin lending by vintage.](image)

**Notes:** Panel A shows monthly aggregate market cap (in black) and the ratio of margin debt to market cap (in blue) for all stocks in sample. Both market cap and margin debt are measured in trillions of yuan. Panel B shows the average ratio of margin debt to initial market cap (measured as the 2009 average at the stock level) for each of the five vintages of the margin lending roll-out. Both market cap and margin debt are measured in trillions of yuan. Vertical lines show the starting date of each vintage, with black, gray, red, blue and green representing Vintages 0, 1, 2, 3 and 4, respectively.
Figure 2: Anticipation Effects of an Increase in Credit Supply

Notes: In the figure above the y-axis displays price, the x-axis displays time, and the vertical line indicates the event date of a credit supply shock. The red lines represent the case of no anticipation effects. The red line on the y-axis is price before the event date. The discrete jump in the red line represents the long-run direct effect of credit supply on price. Gray and black lines portrays two additional cases of anticipation with limited frictions to arbitrage. The gray line represents the case of perfect foresight, in which agents are able to exactly predict the long-run direct effect. The black line represents a case of overshooting, in which agents overshoot the long-run direct effect.
**Figure 3: Market Anticipation of Margin Lending Rollout: Residualized IHS(Market Cap)_{t+1} by Vintage**

Notes: Plots show residuals from regressions of IHS(Market Cap)_{t+1} at the stock-month level on stock fixed effects, month×year fixed effects and dummies for membership in each decile of book equity at the month level. Market cap is measured in yuan. Residuals are calculated from a single regression with all stocks in sample, and plotted separately for Vintages 2, 3, and 4 of the margin lending roll-out and for the set of stocks that were never marginable. Vertical lines show the starting date of each vintage, with red, blue and green representing Vintages 2, 3 and 4, respectively.

**Figure 4: Anticipatory Market Activity: Residualized Turnover by Vintage**

Notes: Plots show residuals from regressions of turnover at the stock-month level on stock fixed effects, month×year fixed effects and dummies for membership in each decile of book equity at the month level. Market cap is measured in yuan. Residuals are calculated from a single regression with all stocks in sample, and plotted separately for Vintages 2, 3, and 4 of the margin lending roll-out and for the set of stocks that were never marginable. Vertical lines show the starting date of each vintage, with red, blue and green representing Vintages 2, 3 and 4, respectively.
Figure 5: Unconstrained Investors’ Anticipation of Margin Lending Rollout: Residualized Institutional Ownership by Vintage

Panel A: Mutual Fund Ownership Share

Panel B: Top 10 Investors Ownership Share

Notes: Plots show residuals from regressions of the proportion of institutional ownership at the stock-quarter level on stock fixed effects, quarter fixed effects and dummies for membership in each decile of book equity at the month level. Residuals are calculated from a single regression with all stocks in sample, and plotted separately for Vintages 2, 3, and 4 of the margin lending roll-out and for the set of stocks that were never marginable. Vertical lines show the starting date of each vintage, with red, blue and green representing Vintages 2, 3 and 4, respectively.
**Figure 6: Differential Anticipation for Predictably Marginable Stocks: Residualized IHS(Market Cap)_{t+1} by Likelihood of Inclusion**

**Panel A: Vintage 2 Stocks**

- **Notes:** Plots show residuals from regressions of IHS(Market Cap)_{t+1} at the stock-month level on stock fixed effects, month×year fixed effects and dummies for membership in each decile of book equity at the month level. Market cap is measured in yuan. Residuals are calculated from a single regression with all stocks in sample, but plotted separately—within stocks ultimately included in Vintages 2, 3 and 4—for stocks with above vs. below median rank on the index that determines inclusion in the vintage. Those with low rank were ex-ante the most likely to be included in the next vintage, whereas those with high rank were ex-ante the least likely to be included. Vertical lines show the starting date of each vintage, with black, gray, red, blue and green representing Vintages 0, 1, 2, 3 and 4, respectively.
Figure 7: Leverage by Likelihood of Inclusion

Notes: Plots show the 90th percentile of leverage across households that hold each stock, averaged, with in each vintage, over stocks with above vs. below median rank on the index that determines inclusion.
**Figure 8: Anticipation Effects with Frictions**

Notes: In the figure above the y-axis displays price, the x-axis displays time, and the vertical line indicates the event date of a credit supply shock. The red lines represent the case of no anticipation effects. The red line on the y-axis is price before the event date. The discrete jump in the red line represents the long-run direct effect of credit supply on price. The black line presents an example of anticipation with significant frictions, for example refinancing frictions in the real estate market. Even if frictions outweigh the benefits of purchasing the asset before the credit supply shock, parallel trends may fail if agents delay purchases to take advantage of the shock itself.
**Figure 9: Optimal Delay in the Housing Market?**

**Panel A: Home Prices by Deregulatory Status**

![Graph of home prices by deregulatory status](image)

**Panel B: Growth Rate of Mortgage Originations by Deregulatory Status**

![Graph of mortgage originations growth rate by deregulatory status](image)

**Notes:** Panel A displays the average yearly home price indices taken across three groups of states determined by the 1997 level of the Rice-Strahan index developed in Rice & Strahan (2010). We consider low regulation states (index=0), medium regulation states (index between 1 and 3) and high regulation states (index=4). The vertical lines represent 1994 and 1997, respectively. Panel B repeats the exercise, but displays average mortgage origination growth rates.

Results from non-myopic difference-in-difference and IV specifications of IHS(Market Cap) on the margin lending roll-out. For our difference-in-difference specifications we report coefficients from the following regression:

$$IHS(Market\ Cap)_{i,t} = \alpha + \beta_0 Margin\ Trading\ Active_{i,t} + \sum_{j=1}^{S} \beta_j D_{i,t+j} + \gamma_i + \delta_t + \varepsilon_{i,t}.$$

For the second stage of IV specifications, we replace Margin Trading Active with IHS(Margin Debt) in the above, and use Margin Trading Active as an instrument for IHS(Margin Debt) in a first stage. Market Cap and Margin Debt are measured in RMB at the stock-month level. Margin Trading Active is equal to one only (i) for stocks that are included in the margin trading roll-out, and (ii) in months after margin trading is active in those stocks. $D_{i,t+j}$ is equal to one if margin trading initially becomes active for stock $i$ in period $t + j$, and zero otherwise. The number of ex-ante effect coefficients indicates the value of $S$ for the regression in question. The myopic approach includes no ex-ante effects, and is equivalent to the collapsed difference-in-difference approaches presented above. Non-myopic specifications include indicators aimed at capturing ex-ante effects for the six months and six quarters leading up to the roll-out for each stock. Standard errors, clustered at the stock and month level, are included in parentheses. Sample covers March 2009-May 2015. Mean of dep. var refers to the mean of IHS(Market Cap)$_t$. Book-equity deciles refer to dummy variables for each decile of book equity in the previous fiscal year. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Results from non-myopic difference-in-difference specifications of either the proportion of institutional ownership or turnover on the margin lending roll-out in the vein of Malani and Reif (2015). We report coefficients from the following regression

$$y_{it} = \alpha + \beta_0 \text{Margin Trading Active}_{it} + \sum_{j=1}^{S} \beta_j D_{i,t+j} + \gamma_i + \delta_t + \epsilon_{it}.$$  

Where $y_{it}$ represents either the proportion of ownership by mutual funds of each stock, the proportion of ownership by the top 10 investors in each stock, or turnover. The first two are at a quarterly frequency, while turnover is at a monthly frequency. Margin Trading Active is equal to one only (i) for stocks that are included in the margin trading roll-out, and (ii) in half-years after margin trading is active in those stocks. $D_{i,t+j}$ is equal to one if margin trading initially becomes active for stock $i$ in period $t+j$, and zero otherwise. The number of ex-ante effect coefficients indicates the value of $S$ for the regression in question. For each outcome, we include a myopic approach with no ex-ante effects and a non-myopic approach with two quarters of anticipation. Sample covers March 2009-May 2015. Mean of dep. var. refers to the mean of $y_{i,t}$ Book-equity deciles refer to dummy variables for each decile of book equity in the previous fiscal year. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

- **Results from non-myopic triple-difference specifications of IHS(Market Cap), on the margin lending roll-out, differentiated by high vs. low ranking stocks amongst those included in each vintage. For our triple-difference specifications we report coefficients from the following regression**

\[
IHS(Market\ Cap)_{t,j} = \alpha + \beta_1 \text{Margin Trading Active}_{t,j} + \beta_2 \text{Margin Trading Active}_{t,j} \times \text{High Rank}_{t,j} + \delta_i + \epsilon_{it}
\]

- **For the second stage of IV specifications, we replace Margin Trading Active with IHS(Margin Debt) everywhere in the above, and use Margin Trading Active and Margin Trading Active$_{t,j} \times$ High Rank$_{t,j}$ as instruments for IHS(Margin Debt) and IHS(Margin Debt)$_{t,j} \times$ High Rank$_{t,j}$ in a first stage. Market Cap and Margin Debt are measured in RMB at the stock-month level. High rank is a dummy variable that indicates stocks in each vintage that are above median rank within the vintage according to the index that determines inclusion. Margin Trading Active is equal to one only if stocks that are included in the margin trading roll-out, and (ii) in months after margin trading is active in those stocks. $D_{t,j}$ is equal to one if margin trading initially becomes active for stock $i$ in period $t + j$, and zero otherwise. The number of ex-ante effect coefficients indicates the value of $5$ for the regression in question. The myopic approach includes no ex-ante effects, and is equivalent to the collapsed difference-in-difference approaches presented above. Non-myopic specifications include indicators aimed at capturing ex-ante effects for the six months and six quarters leading up to the roll-out for each stock. Standard errors, clustered at the stock and month level, are included in parentheses. Sample covers March 2009-May 2015. Vintages 0 and 1 are excluded as inclusion in those vintages was not based upon a pre-defined rule. Mean of dep. var refers to the mean of IHS(Market Cap)$_{t,j}$. Book-equity deciles refer to dummy variables for each decile of book equity in the previous fiscal year. * $p < 0.1$, ** $p < 0.05$, *** $p < 0.01$.**

</table>

Results from non-Myopic difference-in-difference and triple-difference specifications of HSI(Market Cap)_{t-1} as indicators for a placebo treatment and entry to the demarginalization of margin trading. To generate a placebo treatment group, a treatment start date was randomly selected, and the top 150 stocks according to the screening and ranking rules were selected in each exchange using data for the three months prior to that date. Ex-ante specifications labeled "Never Marginable" the top 150 stocks were chosen after excluding any stocks that actually qualified for margin lending under the official demarginalization. In specifications labeled "Pre-Period", no stocks were excluded, but placebo data are chosen only in the period preceding the actual start date of treatment. We report coefficients from the following regressions:

\[ \text{HSI (Market Cap)}_{t-1} = \beta_0 \cdot \text{Placebo Active}_{it} + \beta_1 \cdot \text{Placebo Active}_{it-1} \times \text{High Rank}_{it} + \sum_{\tau=1}^{T} \delta_{\tau} \cdot \text{Placebo Active}_{it-\tau} + \gamma_{\tau} \cdot \text{Book Rank}_{it} + \epsilon_{it} \]

Placebo Active is equal to one for stocks selected as part of the placebo treatment group only in the period after the randomly selected treatment start date. Market Cap is measured in RMB at the stock-month level. High rank is a dummy variable that denotes the above median (top 50) stocks in the placebo treatment group for each exchange. \( \text{Book Rank}_{it} \) is equal to one for placebo treatment stocks if the placebo treatment start date is exactly period \( t \); zero otherwise. The number of ex-ante effect coefficients indicates the value of \( T \) for the regression in question. The myopic approach includes no ex-ante effects. The first five columns omit any interactions with High Rank, non-Myopic specifications include indicators aimed at capturing ex-ante effects for the six months and six quarters leading up to the roll-out for each stock. Standard errors, clustered at the stock and month level, are included in parentheses. Sample covers March 2000-May 2015. Column 2 and 3 are excluded as inclusions in these years was not based upon a pre-defined rule. Mean of dep. var refers to the mean of HSI(Market Cap). Book-equity deciles refer to dummy variables for each decile of book equity in the previous fiscal year. * p < 0.1, ** p < 0.05, *** p < 0.01.
Internet Appendix: For Online Publication

A Replicating the screening-and-ranking procedure using public data

To validate the relevance of the screening and ranking procedure discussed in Section 2.1, we use public stock market data to try to predict the list of marginable stocks for Vintages 2-4. It is worth mentioning that there are a handful of limitations that may prevent us from doing so precisely. First, the exact time window used by the exchange is not clear. However, according to some industry sources, the exchanges use data on a three-month period before the formal announcement of each vintage, although we assume there must be at least some small gap for calculation between the data-collection period and the announcement. Here, we take the end of the most recent month prior to the formal announcement as the end of the three month evaluation period. Second, there is some room at the margins for discretion on the part of the exchanges, with little in the way of published detail. As such, we do not expect to be able to precisely predict inclusion.

For each vintage, we examine the set of stocks that are non-marginable before the vintage is announced. We follow the screening rule and first exclude stocks that do not meet the criteria over the three-month window. Then, we calculate the ranking indicator as specified in Equation 1 for the remaining stocks and rank them into descending order. We denote stock \( i \)'s rank for Vintage \( k \) as \( \text{Rank}^k_i \), where \( k = \{2, 3, 4\} \).

Let \( \tau^k_i \) equal one if \( \text{Rank}^k_i \leq C^k \) and zero otherwise, where \( C^k \) is the number of newly marginable stocks in stock \( i \)'s exchange in Vintage \( k \). That is, \( \tau^k_i \) is the predicted marginable status for stock \( i \) for Vintage \( k \). Define the indicator of actual marginable status as \( D^k_i \), which equals one if stock \( i \) becomes marginable for Vintage \( k \). For the reasons listed above, \( \tau^k_i \) does not perfectly predict \( D^k_i \) for all stocks. Nonetheless, as long as \( \tau^k_i \) is an effective predictor of \( D^k_i \), we can still use it to proxy the anticipation effect of credit supply. To formally test this, we follow Chang et al. (2014) and run the first-stage regression of a fuzzy RD. That is, for Vintage \( k \) and stock \( i \) satisfying the screening criteria,

\[
D^k_i = \alpha_{0l} + \alpha_{1l}(\text{Rank}^k_i - C^k) + \tau^k_i [\alpha_{0r} + \alpha_{1r}(\text{Rank}^k_i - C^k)] + \epsilon_i
\]  

(11)

If \( \tau \) can strongly predict \( D \), we expect \( \alpha_{0r} \) to be close to one and the R-squared of the regression to be high. Table A.I presents the results for each vintage. While the rankings for stocks are done by exchange, we pool together observations from both exchanges to implement their regression. In column (1), the regression is estimated using the sample of stocks for Vintage 2. The point estimate of \( \alpha_{0r} \) is 0.78, and \( R^2 \) equals 0.84, showing that predicted inclusion (\( \tau \)) can effectively forecast the announced inclusion (\( D \)). The results are similarly strong for Vintages 3 and 4. This confirms the

In our analysis, we use the pre-ranking, i.e., \( \text{Rank}_i \), to identify stocks likely-to-qualify for the margin
To test the difference in anticipation effects between early (Vintage 0 and 1) versus late (Vintages 2, 3, and 4) vintages.

\[
\text{IHS(Market Cap)}_{i,t} = \alpha + \beta_0 \text{Margin Trading Active}_{i,t} + \sum_{j=1}^{S} \beta_j D_{i,t+j} \\
+ \eta_0 \text{Margin Trading Active}_{i,t} \times \text{Late Vintage}_i + \sum_{j=1}^{S} \eta_j D_{i,t+j} \times \text{Late Vintage}_i \\
+ \theta_1 BE_{i,t} + \gamma_i + \delta_t + \varepsilon_{it}. 
\] (12)

\( \eta_j > 0 \) provides further evidence for anticipatory effects: suggesting that the later, more predictable vintages saw larger increases in market cap in the months prior to the rollout.

We also estimate IV versions of these specifications, where, in a second stage, we estimate:

\[
\text{IHS(Market Cap)}_{i,t} = \alpha + \beta_0 \text{IHS(Margin Debt)}_{i,t} + \sum_{j=1}^{S} \beta_j D_{i,t+j} \\
+ \eta_0 \text{IHS(Margin Debt)}_{i,t} \times \text{Late Vintage}_i + \sum_{j=1}^{S} \eta_j D_{i,t+j} \times \text{Late Vintage}_i \\
+ \theta_1 BE_{i,t} + \gamma_i + \delta_t + \varepsilon_{it}. 
\] (13)

In a first stage, we include Margin Trading Active_{i,t} and Margin Trading Active_{i,t} \times \text{Late Vintage}_i as excluded instruments for IHS(Margin Debt)_{i,t} and IHS(Margin Debt)_{i,t} \times \text{Late Vintage}_i. These IV estimates provide coefficients that can be interpreted as elasticities.

Table A.II, which shows estimates from the specifications described in Equation (12), displays significant evidence anticipation. In monthly and quarterly specifications, there are positive and highly significant differential ex-ante effects for late vintages, suggesting that later more predictable vintages saw significantly larger anticipatory effects. Additionally, the estimated elasticities—evaluated at the means of margin debt and market cap—suggest that, in the monthly specification, an additional dollar of margin debt is associated with a 1.28 dollar larger increase in market cap for later vintages compared with earlier vintages.
C  Anticipating shadow margin: The peak of the bubble in 2015

While our analysis has been constrained thus far to the official deregulation of margin lending, the notion of anticipation we describe should, in principle, apply to any foreseeable expansion of credit. To conclude our analysis, we briefly consider the expansion of what is often referred to shadow margin: the provision of margin via peer-to-peer platforms distinct from formal brokerages, allowing smaller investors to informally buy any stock on margin. Although the introduction of shadow margin was not as precisely delineated as lending through formal channels, the process expanded rapidly in late 2014 and early 2015. Estimates place shadow margin in 2015 at almost 1 trillion yuan, roughly half of the formal margin amount during at the peak of the bubble.

The patterns in Panel A of Figure A.II (which reproduces the later period of Figure 5) suggest that mutual funds began to increase their relative positions in non-marginable stocks after the introduction of Vintage 4, the final official set of marginable stocks. Similar patterns can be seen for the top 10 investors, to a lesser extent, in Figure 5. We now argue that this buying anticipated the rise in shadow margin lending in the Chinese stock market which was concentrated in these non-marginable stocks. The non-marginable stocks, which had previously under-performed, outperformed the market during the final period prior to the crash (Figure 3).

To show that this is indeed the case, we gather data on shadow margin lending from a peer-to-peer platform that encompassed around 10% of the market during this period. We measure the presence of shadow margin at the stock level using data from a large technology provider. This technology company routed the trades of 180 peer-to-peer platforms that provided leverage for stock purchases. Each platform had a master account which qualified for margin with the stock exchange. This master account was subdivided into smaller managed accounts for individual households that could then buy stocks on margin provided by the platform. The technology company managed the website and routing of trades. As a result, it aggregated for us all the buys and sells from the 180 peer-to-peer platforms. They calculate for us the net buys and sells each day and the cumulative net buys and sells over time for each stock, which we then use as a proxy for shadow margin. This shadow margin figure is not identical to the margin balance data from the exchanges since the net buys and sells is marked to market daily. But it does provide a measure of shadow margin activity across different stocks. In our analysis, we scale shadow margin by a factor of 10 to reflect that the peer-to-peer platform we collected data only accounts for 10% of the market.

Panel B of Figure A.II plots shadow margin debt for the different vintages, and for all stocks that were not part of any vintage, in the latter part of our sample. Unsurprisingly, shadow margin begins to expand later in the sample, around the end of 2014, suggesting that it is not a major concern for our primary analysis.
Further, the majority of shadow margin debt is concentrated in non-marginable stocks, suggesting that mutual funds and unconstrained investors were at least matching—if not anticipating—the flows of shadow margin debt. These findings are reminiscent of Brunnermeier & Nagel (2004) and Griffin et al. (2011) who found that hedge funds rather than shorting internet stocks actually overweighted internet stocks going into the dot-com bubble. The collection of these forces surely contributed to the dramatic surge and subsequent crash in the non-marginable stocks (along with the rest of the market) in 2015.
D Appendix Figures

**Figure A.1: Limited Evidence of Indirect Effects**

**Panel A: Vintage 2**

**Panel B: Vintage 3**

**Panel C: Vintage 4**

Notes: Plots show the average holdings in yuan of investors in stocks that were never marginable at any point during the sample. All data based on accounts of investors who made margin trades at some point during our sample period. We focus on Vintages 2, 3, and 4 in Panels A, B, and C, respectively. In each panel, the black line shows the average among investors who had holdings in some stock within the vintage in question at any point in our data prior to the month the vintage was opened to margin lending. The gray line shows the average among investors who had no holdings in any stock within the vintage at any point in our data prior to the introduction of margin lending. In each plot, we limit to accounts that are present in our data at least one year prior and one year after margin trading was allowed for the vintage in question.
Panel A: Residualized Mutual Fund Ownership From Mid-2013 On

Panel B: Aggregate Shadow Margin Debt

Notes: Panel A shows residuals from regressions of the proportion of mutual fund ownership at the stock-quarter level on stock fixed effects, quarter fixed effects and dummies for membership in each decile of book equity at the month level. Residuals are calculated from a single regression with all stocks in sample, and plotted separately for Vintages 2, 3, and 4 of the margin lending roll-out and for the set of stocks that were never marginable. Panel B shows aggregate shadow margin debt by vintage in trillions of yuan, calculated by scaling our observed shadow margin debt by a factor of 10. Vertical lines show the starting date of each of the last two vintages, with blue and green representing Vintages 3 and 4, respectively.

Coefficients from predictive regressions of marginable membership for Vintages 2–4 as,

$$D_i^k = \alpha_{0l} + \alpha_{1l}(Rank_i^k - C^k) + \tau_i^k[\alpha_{0r} + \alpha_{1r}(Rank_i^k - C^k)] + \epsilon_i$$

where $k = \{2, 3, 4\}$. $D_i^k$ is the indicator, which equals one if stock $i$ is added to the marginable list in Vintage $k$; $Rank_i^k$ is stock $i$’s ranking that we produce based on exchanges’ procedure. $C^k$ is the number of stocks added to the marginable list in Vintage $k$. $\tau_i^k$ equals one if $Rank_i^k - C^k \leq 0$; otherwise zero (i.e., predicted marginable status based on our ranking). The sample only includes non-marginable stocks that satisfy screen criteria in the evaluation period. For each extension, we run the regression using the pooled sample of stocks in Shanghai and Shenzhen. The evaluation window is 2014/06/01-2014/08/31, 2013/06/01-2013/08/31, and 2012/10/01-2012/12/31, for the fourth, third, and second vintage, respectively. The point estimate of is reported and robust standard errors are reported in parentheses. * $p < 0.10$, ** $p < 0.05$, *** $p < 0.01$.

Results from non-myopic triple-difference specifications of IHS(Market Cap) on the margin lending roll-out, differentiated by early versus late vintages. For our triple-difference specifications we report coefficients from the following regression:

\[
IHS(Market\ Cap)_{it} = \alpha + \beta_i \text{Margin Trading Active}_{it} + \eta_j \text{Margin Trading Active}_{it} \times \text{Late Vintage}_{it} + \sum_{j=1}^{6} \beta_j D_{i,t+j} + \eta_j D_{i,t+j} \times \text{Late Vintage}_{it} + \gamma_i \times \text{Book-Equity Deciles}_{it} + \delta_i \times \text{Month \\times Year Fixed Effects}_{it} + \epsilon_{it}
\]

For the second stage of IV specifications, we replace Margin Trading Active with IHS(Margin Debt) everywhere in the above, and use Margin Trading Active and Margin Trading Active × Late Vintage as instruments for IHS(Margin Debt) and IHS(Margin Debt) × Late Vintage in a first stage. Market Cap and Margin Debt are measured in billions of dollars at the stock-month level. Late Vintage is a dummy variable that indicates stocks in Vintages 2, 3 and 4. Margin Trading Active is equal to one if margin trading initially becomes active for stock \(i\) in period \(t + j\) and zero otherwise. The number of ex-ante effect coefficients indicates the value of \(S\) for the regression in question. The myopic approach includes no ex-ante effects, and is equivalent to the collapsed difference-in-difference approaches presented above. Non-myopic specifications include indicators aimed at capturing ex-ante effects for the six months and six quarters leading up to the roll-out for each stock. Standard errors, clustered at the stock and month level, are included in parentheses. Sample covers March 2009 to May 2015. Mean of dep. var refers to the mean of IHS(Market Cap). Book-equity deciles refer to dummy variables for each decile of book equity in the previous fiscal year. * \(p < 0.10\), ** \(p < 0.05\), *** \(p < 0.01\).
