Abstract

How do differences of opinion affect asset prices? Do investors earn a risk premium when disagreement arises in the market? Despite their fundamental importance, these questions are among the most controversial issues in finance. In this paper, we use a novel data set that allows us to directly measure the level of disagreement among Wall Street mortgage dealers about prepayment speeds. We examine how disagreement evolves over time and study its effects on expected returns, return volatility, and trading volume in the mortgage-backed security market. We find that increased disagreement is associated with higher expected returns, higher return volatility, and larger trading volume. These results imply that there is a positive risk premium for disagreement in asset prices. We also show that volatility in and of itself does not lead to higher trading volume. Instead, only when disagreement arises in the market is higher uncertainty associated with more trading. Finally, we are able to distinguish empirically between two competing hypotheses regarding how information in markets gets incorporated into asset prices. We find that sophisticated investors appear to update their beliefs through a rational expectations mechanism when disagreement arises.

1. Introduction

Understanding how disagreement affects security prices in financial markets is one of the most important issues in finance. When participants in a market disagree with each other, an investor who goes out on a limb and takes a position based on his unique expectations could face a greater risk of being wrong. Such trading risk or adverse-selection risk differs fundamentally from the traditional types of market risks that are priced in asset values. This means that investors who trade when disagreement exists could require additional compensation for bearing this risk. Despite the fundamental nature of this issue, though, significant controversy in the literature still remains about how disagreement risk affects expected returns and asset prices.

On one hand, an extensive theoretical literature implies that divergence in beliefs or opinions should lead to a positive risk premium. For example, Varian (1985, 1989), Abel (1989), and many others argue that the equity premium puzzle could be explained in terms of a risk premium for heterogeneous beliefs or differences of opinion, or both. As such, it appears that investors should be compensated for bearing trading risk or the risk due to adverse selection when disagreement arises.

On the other hand, Miller (1977) argues that differences of opinion in the market can lead to lower expected returns (higher prices) when short-sale constraints are present. This occurs because pessimists sit out of the market and asset prices reflect only the valuation of optimists. Chen, Hong, and Stein (2002) and Diether, Malloy, and Scherbina (2002) find compelling support for the Miller hypothesis in several markets in which there are binding short-sale constraints. However, Boehme, Danielsen, Kumar, and Sorescu (2009) and Avramov, Chordia, Jostova, and Philipov (2009) find evidence to the contrary. Either way, this still leaves open the more fundamental issue of how disagreement is priced in general markets without significant short-sale constraints, illiquidity, or other trading frictions.

To best resolve the controversy, we would ideally want to study a market with several key characteristics. First, the market should be highly liquid and essentially free from short-sale constraints. Second, the key drivers of an asset’s value should be easily defined and common knowledge. Finally, disagreement about these key drivers among the institutions that actually trade the assets should be directly observable. This last condition bypasses the measurement uncertainty that results when an indirect proxy for disagreement is used.

In this paper, we analyze a time series of prepayment speed (PSA) forecasts issued by major Wall Street mortgage dealers and then consider how disagreement affects expected returns, return volatility, and trading volume in the agency mortgage-backed security (MBS) market. This market provides unique advantages. First, because the PSA forecasts are given for various interest rate scenarios and the mortgage-backed securities are guaranteed by the US government, credit risk and interest rate risk do not affect the dealers’ PSA estimates. Thus, the only cash flow uncertainty associated with a mortgage-backed security is the timing of prepayments. In turn, the timing of cash flows is a key factor affecting how investors value mortgage-backed securities. This allows us to precisely correlate disagreement with the return characteristics of mortgage-backed securities. Second, the PSA forecasts are made by members of the trading desks at the same institutions that intermediate the trade of mortgage-backed securities. Therefore, we know directly what the dealers’ best estimate is for the key input to valuing the assets under consideration, which allows us to best study the relation between disagreement and asset prices.

Using PSA estimates from July 1993 to January 2012, we construct a disagreement index and find a surprisingly high level of disagreement among the participants in the survey. We show that disagreement is time-varying, correlated with financial and macroeconomic variables, and magnified when major events occur in financial markets (e.g., the failure of Long-Term Capital Management, the September 11 attacks, and Lehman Brothers default).

Following this, we study whether disagreement is priced in the market. To examine whether disagreement about prepayment rates affects the expected returns of mortgage-backed securities, we use the standard approach of regressing ex post realized returns on the ex ante measures of disagreement and other proxies for risk premia. For disagreement to be priced in expected returns, the disagreement index should have predictive power for subsequent returns on mortgage-backed securities even after controlling for the other ex ante risk premium proxies. Using a proprietary data set of daily returns on the Fannie Mae To Be Announced (TBA) security closest to the current coupon mortgage rate, we construct a measure of monthly returns. Including the disagreement index in the regression significantly increases the predictive power, and the coefficient on the disagreement variable is positive and highly significant. Based on this, we can conclude that increased disagreement is associated with higher expected returns, which supports the thesis that disagreement is associated with a positive risk premium, as posited by Varian (1985, 1989) and Abel (1989). Further, because we control for several measures of market risk in our empirical specification (e.g., interest rate risk, the S&P 500 volatility index (VIX), the monthly excess return on the CRSP value weighted index, and the effective duration of the Lehman/Barclays US MBS index), this implies that disagreement risk is likely to be a form of trading risk or risk due to adverse selection.

Finally, we analyze the relation between disagreement, return volatility, and trading volume. We use a simple vector autoregression (VAR) framework in which we include all three variables with lags and controls. We find that increasing disagreement is followed by periods of higher volatility and trading volume. This is consistent with Shalen (1993) and Zapatero (1998), who posit that disagreement and price volatility should be positively correlated. More strikingly, though, we find that volatility in and of itself does not lead to higher trading volume. Instead, it is only when more disagreement exists that trading volume increases. Our findings lend support to the predictions of Harris and Raviv (1993), that differences in opinion is the primary channel through which uncertainty leads to higher trading volume. To our knowledge, our study is the first to empirically show the importance of this channel. Our results are also consistent with the empirical findings of Kandel and Pearson (1995), who find that dispersion in analyst forecasts affects trading volume, particularly around anticipated earnings announcements. Interestingly, we find that higher trading volume is associated with lower subsequent disagreement. We view this as intuitive: As investors learn through trade, they have opportunities to update their beliefs about the drivers of asset value.

---

1 Providers of PSA estimates included Barclays, Bank of America, Bear Stearns, Credit Suisse, Deutsche Bank, Donaldson, Lufkin, and Jenrette, Goldman Sachs, HSBC, JP Morgan Chase, Lehman Brothers, Merrill Lynch, Morgan Stanley, Nations Bank, Prudential, Greenwich Capital, Salomon Brothers, Smith Barney, and UBS Warburg. These dealers intermediated the majority of trade in MBS markets during the period that we analyze in this paper.

2 The To Be Announced market is a highly liquid market in which buyers and sellers agree on the future sale prices of mortgage-backed securities but do not specify which particular assets will be delivered. Details about this market are in Section 3.2.
Besides providing evidence that disagreement is associated with a positive risk premium, we are able to distinguish between two competing hypotheses regarding how information in markets gets incorporated into asset prices. As Banerjee (2011) highlights, investors can update their beliefs via a rational expectations mechanism or they can agree to disagree, which results in persistent differences in opinion. According to Banerjee (2011), these two mechanisms can be distinguished empirically by comparing how return-volume characteristics vary with disagreement in the market. We find that higher disagreement is associated with higher expected returns, higher subsequent return volatility, and higher trading volume. These results directly support the rational expectations channel. Especially given our finding that higher trading volume is associated with lower subsequent disagreement, rational investors are more likely to learn from prices and opinions in the market, updating their beliefs using Bayes’ rule via a rational expectations channel.

The rest of the paper is organized as follows. In Section 2, we review the literature in this area to highlight our contribution. In Section 3, we review the data that we collect and some important institutional details regarding the estimation of prepayment speeds, the agency mortgage-backed security markets, and the TBA market. In Section 4, we construct a measure of disagreement and describe its empirical properties. In Section 5, we characterize the relation between disagreement and expected returns, return volatility, and trading volume. Section 6 provides some concluding remarks.

2. Literature review

2.1. Disagreement and learning

At any time, disagreement could arise due to heterogeneous beliefs or persistent differences of opinion. Much attention has been devoted to whether the former eventually leads to asymptotic agreement when learning occurs. Starting with Blackwell and Dubins (1962), Aumann (1976), and Geanakoplos and Polemarchakis (1982), investigators have focused on conditions that make disagreement impossible in a rational setting. As Aumann (1976) shows in a remarkably clear way, if agents share a common prior and have common knowledge of each other’s posterior beliefs, they cannot agree to disagree. Geanakoplos and Polemarchakis (1982) extend this analysis showing that communication, either direct or indirect, results in an equilibrium with common posterior beliefs. In their words, “we can’t disagree forever”.

Later work, however, shows that permanent disagreement can arise even when agents have common priors and observe the same time series of public information. As Acemoglu, Chernozhukov, and Yildiz (2006) point out, many empirical settings exist where such permanent disagreement arises. As such, they study a setting in which individuals are uncertain about the interpretation of the signals they receive, which implies they have non-degenerate probability distributions over the conditional distribution of signals given the underlying parameter of interest. In such case, Acemoglu, Chernozhukov, and Yildiz (2006) show that agreement could be impossible, despite the fact that all agents update their beliefs as Bayesians.

Given this, at any time there could be several mechanisms whereby disagreement in a financial market could arise. First, investors could update according to Blackwell and Dubins (1962), but at the time of observation investors’ beliefs have yet to fully converge. Second, investors update their beliefsrationally, but because they are uncertain about the quality of their signal, their beliefs could fail to converge. Last, market participants can simply “agree to disagree” in that they observe the same public information but adhere to different models. This etiology can have an added behavioral component, but has been used by Varian (1985), Harris and Raviv (1993), and David (2008).

Given this, the evolution of beliefs can occur via two learning mechanisms. Investors could learn over time via a rational expectations channel in which heterogeneous beliefs are more likely to converge. Alternatively, disagreement could persist as differences of opinion lead to dispersion in forecasts. As pointed out by Banerjee (2011) in a theoretical model, these two channels can be distinguished empirically. With the rational expectations channel, Banerjee (2011) predicts that increased disagreement should induce higher expected returns, higher volatility, higher market betas, and higher covariance between volume and absolute returns, but lower return autocorrelation. When investors agree to disagree (i.e., differences in opinion persist), the opposite trends should be present. In both channels, disagreement is positively correlated with trading volume.

2.2. Disagreement and risk premia

Much of the extant theoretical work posits that a positive risk premium should be associated with disagreement in the market. Following the seminal work of Mehra and Prescott (1985), several authors rationalize the equity premium puzzle by considering that investors could have heterogeneous beliefs or differences of opinion. Varian (1985) considers an Arrow-Debreu economy with agents who have different subjective probabilities. In equilibrium, an increase in the range of probability beliefs typically decreases asset values, as long as risk aversion is not abnormally high. As such, disagreement is associated with a positive risk premium under reasonable preferences. Varian (1989) provides an elegant summary of these results.

Likewise, Abel (1989) investigates an equilibrium asset pricing model in which investors’ demands for risky stocks and riskless bonds depend on their subjective beliefs about payoffs to the risky capital. When beliefs are more heterogeneous, this reduces the stock’s price, and can dramatically increase the equity premium relative to bonds. Abel (1989) concludes that the equity premium under homogeneous beliefs understates the premium that would arise under heterogeneous beliefs.

Subsequent theoretical work has confirmed these findings. Basak (2005) provides a good survey. More recently, David (2008) studies a general equilibrium exchange economy in which two types of agents have heterogeneous beliefs. The agents have a difference of opinion and agree
to disagree, in that they update their beliefs differently about the state of the economy even though they observe the same signals. Agents trade and can speculate on the relative accuracy of their respective models. David (2008) shows that less risk-averse agents speculate more, but they demand higher risk premia. Chen, Joslin, and Tran (2010) study an equilibrium model with affine disagreement about fundamentals, which allows them to consider stochastic disagreement about growth rates, volatility dynamics, and the likelihood and size of jumps. They show that the risk premium depends on whether disasters strike. In normal times, optimistic agents accumulate wealth and there is a decline in the risk premium. When disasters strike, pessimistic agents become wealthier, which causes the risk premium to increase.

One important exception in this literature is Miller (1977), who posits that short-sale constraints should cause disagreement to have a positive effect on stock prices. The intuition is that when pessimists are forced to sit out of the market, stock prices reflect the demand from optimists only, which causes prices (returns) to increase (decrease). This intuition is supported in Liu and Seasholes (2011), who study dual-listed shares in China and Hong Kong. They show that when there is a short-sale ban in China, the prices of Chinese stocks are 1.8 times higher compared with those in Hong Kong.

Miller (1977) has been tested in several empirical studies and has been shown to be plausible. Chen, Hong, and Stein (2002) develop a stock market model in which an increase in divergence of opinion results in a decrease in the breadth of stock market ownership, causing a high stock price and a lower expected return. Then, they show empirically that reducing the breadth of mutual fund ownership of stocks forecasts a lower stock return. Diether, Malloy, and Scherbina (2002) analyze the role of dispersion in analysts’ earnings forecasts in predicting the cross section of future stock returns. They find that stocks with higher dispersion in analysts’ earnings forecasts earn significantly lower future returns than otherwise similar stocks. Park (2005) extends this work by testing whether the aggregate stock market also becomes overpriced when differences in expectations are high. According to Park (2005), the dispersion in expectations among market analysts has predictive power for future stock returns: Higher dispersion predicts lower stock returns. Similarly, Yu (2011) uses the Institutional Brokers’ Estimate System (I/B/E/S) database on analyst forecast and finds that the ex post market return is negatively related to the bottom-up disagreement.

These findings have led others to study disagreement and expected returns in other settings where short-sale constraints exist. Moeller, Schlingemann, and Stulz (2007) study the impact of divergence of opinion on acquirer returns in mergers and acquisitions. They find that increasing diversity of opinion about an acquirer’s value causes the acquirer’s return in stock payment acquisitions to decrease but has no effect in cash transactions. Chatterjee, John, and Yan (2012) show that the total takeover premium, pre-announcement target stock price run-up, and post-announcement target stock price run-up are all higher when investors have a higher divergence of opinion. They use analysts forecasts, change of breadth of mutual fund ownership, and idiosyncratic volatility as three proxies for divergence of analyst opinions.

In contrast, Avramov, Chordia, Jostova, and Philipov (2009) show that the negative relation between dispersion in analysts’ forecasts and stock returns could be simply explained by financial distress risk. Specifically, they show that the profitability of dispersion-based trading is only high when credit conditions deteriorate and is concentrated in a small number of firms with the worst credit ratings. However, the authors find that when their dispersion measure is adjusted by credit risk, even for this small group of firms, the negative dispersion-return relation disappears. Likewise, Boehme, Danielsen, Kumar, and Sorescu (2009) demonstrate a positive relation between dispersion of beliefs and expected returns, after controlling for short interest and investor recognition as proxied by institutional ownership.

Given this, the support for Miller (1977) is mixed. However, the more fundamental issue is left open of how disagreement is priced in general markets without short-sale constraints, illiquidity, or other trade frictions. As described by Fama and French (2007), disagreement or differences in tastes can rationalize empirical deviations from the capital asset pricing model (CAPM) in either direction. In their framework, sophisticated investors choose the correct tangency portfolio, whereas unsophisticated investors choose portfolios that deviate. Unless the unsophisticated investors choose the right portfolio in aggregate on average, the observed market portfolio deviates from optimal. Fama and French (2007) posit that empirical deviation from the CAPM, either to portfolios with higher expected returns or lower, can be explained by the disagreement by unsophisticated investors. As such, it remains an unresolved issue whether disagreement is associated with a risk premium empirically.

2.3. Disagreement, trading volume, and price volatility

The earlier literature, both theoretical and empirical, shows a positive relation between disagreement, trading volume, and price volatility. Harris and Raviv (1993) study the effect of news announcements on trading prices and volume. They assume that traders receive the same common information but differ in the way they interpret the information. In addition, each trader believes absolutely in his own interpretation, so there is difference in opinion. Some of their key findings are that absolute price changes and volume are positively correlated and that absolute changes in the mean forecast of the final payoff and volume are positively correlated.

Shalen (1993) examines a two-period noisy rational expectations model of a futures market and studies the effect that dispersion in expectations has on price volatility and trading volume. Higher dispersion causes higher price volatility, has higher expected trade volume, and increases the correlation between absolute price changes and both contemporaneous and lagged trading volume.

and show increases in trading volume, even when there are no changes in price. The authors posit that this occurs because traders are using different likelihood functions when they Bayesian update.

Zapatero (1998) considers a model with two logarithmic utility maximizers that observe aggregate consumption but disagree about its expected rate of change. Additional information, which induces heterogeneous beliefs, causes higher volatility of interest rates in the economy.

Finally, Banerjee and Kremer (2010) study the relation between disagreement and the dynamics of trade in a theoretical model in which investors differ about the interpretation of public signals. They show that disagreement exacerbates volatility and leads to higher trading volume and that a positive correlation exists between volatility and trading volume.

3. The data

In this paper, we focus on generic agency MBS in which the monthly principal and interest payments are pooled in a pass-through and distributed to investors on a pro-rata basis. The speed at which homeowners prepay their mortgages is a key driver of value for these securities. In what follows, we describe PSA estimates that were made by major MBS dealers for GNMA mortgage-backed securities. We then describe how we construct a return series of FNMA forward contracts that are traded in the TBA market.

3.1. Prepayment speed forecasts

In the MBS market, prepayments speeds are typically quoted according to the PSA convention in which an annualized constant prepayment rate (CPR) is adjusted for the age of the underlying mortgages. New mortgages tend to have very low prepayment speeds and the rate of prepayment rises with age until the mortgages become seasoned, at which point the rate of prepayment remains constant. The PSA benchmark curve was introduced in the 1980s and is often referred to as the 100% curve. At 100%, the prepayment rate starts at 0% for new mortgages, rises by 0.2% per month until month 30, after which the prepayment speed remains constant at 6%. PSA estimates are quoted relative to this benchmark. For example, a GNMA MBS with a PSA of 200% would experience prepayments at a rate twice that of the usual benchmark rate and a GNMA MBS with a PSA of 2% would experience prepayments at a rate that is half the usual benchmark rate.

The expected rate of mortgage prepayment is a key driver of value for valuing MBS but is challenging to forecast. Many factors affect prepayments: home sales, refinancings, defaults, and curtailments. In turn, these are driven by changes in housing supply, mobility, inflation, interest rates, income, employment, and consumer confidence. Estimating prepayment speeds requires sophisticated modeling and, given the degree of complexity involved, could be a significant source of heterogeneous beliefs about the value of a generic MBS.

Major Wall Street dealers in the MBS market participate in a monthly survey, in which they provide Bloomberg with their best estimate of what the PSA would be for a generic GNMA MBS with a given coupon rate. PSA estimates are given for several interest rate scenarios, ranging from 300 basis points below the current rate to 300 basis points above. As such, the forecasts not only reflect the dealers’ expectations of current prepayment speeds, but also how those speeds would change in response to interest rate shocks. This has important ramifications to our analysis. Because the PSA estimates offered by the dealers vary with interest rate changes, any difference of opinion or beliefs that they exhibit is only a function of their calculation of prepayment risk, not of expected interest rate dynamics. As such, the dealers’ opinions regarding the prepayment speeds are the only source of variation driving returns of the MBS. This allows us to study the relation between disagreement and asset prices (Section 5).

Table 1 provides an illustration of the prepayment forecasts provided by survey participants for a generic GNMA I 4.0% pass-through security as of January 31, 2012. Fig. 1 plots the forecasts. Not surprisingly, forecasted prepayment speeds are very sensitive to changes in interest rates. As interest rates decline, PSA forecasts increase and vice versa. More interestingly, however, considerable cross-sectional variation exists in the pattern of PSA forecasts across dealers. In particular, these PSA forecasts differ by a factor of roughly two at current and lower rate levels, but they tend to converge for rate levels substantially above the current rate level.

Another way to compare prepayment forecasts is to consider measures based on normalized values. For each date and each MBS, we normalize the PSA forecasts provided by a participant in the survey by their PSA forecast for the current rate level. As such, the normalized value represents the relative change or slope in the PSA forecast for a given change in the level of rates. Fig. 2 plots the normalized version of the data in Table 1. Even with this normalization, Fig. 2 shows that significant cross-sectional variation remains across the various dealers in terms of their estimates of the sensitivity of prepayment speeds to changes in the level of mortgage rates.

Fig. 3 provides three more snapshots of disagreement during extreme market events: the failure of Askin Capital Management in 1994, the attacks of September 11, 2001, and the failure of Lehman Brothers in 2008. In the top three plots, substantial cross-sectional variation exists in

----

4 Although slight differences could exist in the characteristics of the mortgage-backed securities for which the dealers provide forecasts, these differences have a negligible effect on prepayment speeds. This is because any mortgage-backed security that does not have a generic prepayment speed behavior is excluded from the pool of mortgages that are traded in the TBA markets and for which dealers have provide forecasts. Instead, mortgage-backed securities with non-generic prepayment behavior are traded in the separate specified pool market (Hayre, 2001).

---

Footnote:

For in-depth discussions of pass-through securities and the MBS market, see Hayre (2001) and Fabozzi, Bhattacharya, and Berliner (2007).
An example of the Public Security Association (PSA) forecasts provided by survey participants.

This table shows the PSA forecasts provided by the survey participants on January 31, 2012 for a 4% Government National Mortgage Association (Ginnie Mae; GNMA) mortgage-backed security. The PSA forecasts are given for term structure scenarios ranging from an upward shift of 300 basis points to an upward shift of 300 basis points. The PSA forecasts for the current term structure are given in the column denoted by zero. Maturity denotes the weighted-average maturity of the mortgages underlying the GNMA mortgage-backed security. Coupon denotes the weighted-average coupon or mortgage rate of the mortgages underlying the GNMA mortgage-backed security.

The very nature of the mortgage pass-through market inherently makes it unlikely that differences in access to public information drive variation in PSA estimates. All of the dealers in the survey are large financial institutions that have devoted extensive resources to the mortgage market, and each has the ability to obtain all publicly available information about the term structure of interest rates, interest rate forecasts, volatility, fixed income markets, mortgage prepayment rates, market liquidity, funding availability, and macroeconomic fundamentals. As such, the inputs to most PSA models are readily available to the dealers.

Variation in estimates is unlikely to rest on access to private information. This is simply because very little private information is available to anyone about the mortgage pools underlying the MBS or TBA markets. For example, the generic pools traded on a forward basis in the TBA market tend to be based on recently originated mortgages for which there is little prepayment history. In addition, the dealers generally do not hold or service the mortgage pass-through securities for which they provide forecasts. Thus, they are likely to have little or no private information about the performance of the underlying mortgages. Finally, all of the data about the characteristics of individual mortgage borrowers (such as income, FICO score, appraisals, etc.) are readily available to all market participants.

Taken together, these considerations suggest that asymmetric information is unlikely to drive disagreement about prepayment speeds. Instead, a more likely explanation is that variation in PSA estimates is driven by differences in interpretation and beliefs about the common set of information available to them. These differences in interpretation and
beliefs could manifest themselves as differences in the assumptions or the structure of the models that each dealer uses to estimate mortgage prepayments, or both.

Finally, one concern that could arise is whether the dealers have an incentive to disclose their best estimate of prepayment speed truthfully. We believe that they do. First, as Table 2 suggests, none of the dealers systematically provides different forecasts from their contemporaries. Second, based on a time series of disagreement that we present in Section 4, times of larger variation in estimates correspond to large economic events in which uncertainty is present in the market. Last, the dealers in our study generate substantial revenue from intermediating MBS trade, but they hold little inventory for proprietary trading. Because the PSA estimates are observable to potential clients of the dealers and provide a signal of

5 For example, during the period 2007–2013, brokers and dealers held only between 1.37% and 3.92% of the total agency- and GSE-backed securities (Federal Reserve Statistics Release, 2013).
technical expertise, the dealers have a strong incentive to demonstrate their skills as they compete for order flow.

3.2. Returns on TBA securities

The TBA market is an attractive setting to study returns on MBS, as it is such a highly liquid market. In a TBA trade, the buyer and seller agree on a future sale price, but they do not specify which particular securities will be delivered. Instead, only five additional parameters are promised: the settlement date, issuer, maturity, coupon, and par amount. According to Vickery and Wright (2010), this convention simplifies trade, as well as ameliorates asymmetric information conflicts in the MBS market, leading to higher agency MBS liquidity. In the context of our analysis, though, this makes our study of the relation between disagreement and returns more precise. That is, because the TBA market is so liquid, we can be confident that the asset pricing results we find are not merely due to time-varying transaction costs or other trading frictions.

To measure the returns on mortgage-backed securities, we make use of a proprietary data set provided to us by a major fixed-income asset management firm. This data set consists of daily returns on Fannie Mae TBA’s closest to the current coupon mortgage rate. Because TBAs are forward contracts, the return series consists of the return from going long a one-month TBA, investing the TBA price in a riskless margin account, and then rolling the portfolio over every month on the monthly TBA settlement date. Constructing it this way provides continuity over the monthly roll date in the TBA settlement. We then compute monthly returns by aggregating the daily returns during the month.

4. Measuring disagreement

Our extensive data set of PSA forecasts provides us with a unique opportunity to measure the amount of disagreement in the market directly. Not only does the data set cover a broad cross section of dealers over nearly 20 years, but a number of key features of the data also allow us to obtain more accurate measures of disagreement. First, each PSA forecast is conditional on a specific term structure scenario. Thus, we can compare forecasts across dealers while holding fixed assumptions about the evolution of the term structure. Second, because all of the forecasts are visible in the Bloomberg system, dealers are aware of the extent to which they disagree with other dealers. Finally, and most important, because dealers provide multiple forecasts for each pass-through security, we can normalize each dealer’s forecasts before estimating cross-sectional variation among dealers. This allows us to control for the possibility that the levels of PSA forecasts vary across dealers because of model calibration issues instead of actual disagreement. The mortgage prepayment models used by the Wall Street dealers all require extensive calibration, and each firm likely has a different approach from the others. For example, some dealers calibrate their models using the Treasury yield curve for discounting purposes and to project interest rates forward, whereas others use the swap curve for the same purpose. These differences could easily result in dealers having different calibrations even if the current yield curve is held fixed. Normalization allows us to eliminate the fixed effects among different dealers when we construct a disagreement index.

We construct a monthly disagreement index based on the cross-sectional dispersion among dealers in their normalized PSA forecasts. Specifically, we first identify the GNMA coupon that is closest to the current yield of par mortgage-backed securities (the current coupon) and for which three or more dealer forecasts are available. Generally, the GNMA closest to the current coupon tend to have the greatest homogeneity across dealers in terms of their maturity, pricing, and information availability. Then, for each dealer providing forecasts for the GNMA with the closest coupon, we take the ratio of the PSA forecast for the −100 basis point scenario to the PSA for the +100 basis point scenario. Thus, this ratio is a measure of the relative (normalized) change in prepayment forecast as rates move from 100 basis points above the current level of interest rates to 100 basis points below. Alternatively, this ratio can be viewed as a measure of the slope or sensitivity (duration) of prepayments to changes in interest rates, in the spirit of a difference-in-differences measure. Finally, we compute the simple standard deviation of the ratios across dealers providing forecasts for that month. We repeat the same process for all 223 months in the study period to form the index.

The top panel of Table 3 presents summary statistics for the disagreement index, and Fig. 4 plots its time series. The index has a number of interesting features that could provide some insight into the nature of disagreement in financial markets. First, a surprisingly high level of disagreement exists among the participants in the survey. The average value of the index is 40.29%, and the median value is 35.43%. Thus, even after normalizing the data, wide dispersion is evident among the dealers in their views about changes in prepayment rates. Second, considerable time series variation exists in the amount of disagreement among dealers. In particular, the index varies from a low of 1.96%, reflecting almost perfect agreement among dealers, to a high of 138.60%, representing extreme diversity among dealers in terms of their forecasts. The standard deviation of the index is 24.80%. Thus, disagreement is a dynamic phenomenon. Finally, disagreement among the dealers tends to be persistent in nature: The first-order serial correlation coefficient for the index is 0.6298. Meanwhile, the disagreement index is also strongly mean reverting as evidenced by the serial correlation of monthly changes in the index (−0.455). Intuitively, this suggests that the persistence of a period of higher (or lower) disagreement can be measured in terms of months, rather than years.6

As a robustness check, we also computed an alternative disagreement index by first computing the cross-sectional variance across dealers of their normalized PSA for the −100, −50, +50, and +100 basis point scenarios and then averaging the variances across the four scenarios and computing the overall standard deviation. The empirical results obtained using this alternative measure of the disagreement index, which are available in the online Appendix, are virtually the same as those we report here.

---

6 As a robustness check, we also computed an alternative disagreement index by first computing the cross-sectional variance across dealers of their normalized PSA for the −100, −50, +50, and +100 basis point scenarios and then averaging the variances across the four scenarios and computing the overall standard deviation. The empirical results obtained using this alternative measure of the disagreement index, which are available in the online Appendix, are virtually the same as those we report here.
Fig. 4 also shows that there is a strong episodic nature to periods of higher disagreement. In particular, the graph illustrates that peaks in the level of disagreement tend to coincide with major events in the mortgage and financial markets. Important examples include the mortgage crisis in early 1994 during which the prominent mortgage hedge fund Askin Capital Management failed. Similarly, the highest level of disagreement during the study period occurred in August 1998 during the Long Term Capital Management crisis in the financial markets. Other major events associated with high levels of disagreement include the attacks of September 11, 2001 and the Lehman Brothers default of September 2008. Clearly, disagreement increases during times of extreme uncertainty in the financial markets.

To explore this in more depth, we examine the relation between the disagreement index and a number of key financial and macroeconomic variables that could affect aggregate prepayment behavior. It is important to stress that in estimating this regression, we are not implying causality in the relation between the level of disagreement and these financial and macroeconomic variables. In fact, the level of disagreement and the financial variables are likely all endogenously determined. Instead, our objective is simply to describe the contemporaneous relation between the disagreement index and the other variables.

Table 4 reports the results from the regression and lists the independent variables that we include. As shown, a number of the variables are significantly related to the disagreement index. For example, the mortgage refinancing index is positively related to the level of disagreement. This is intuitive because an increase in prepayments is likely to result in greater dispersion among dealers in their estimates of subsequent prepayments. Similarly, both of the volatility measures are significantly related to the disagreement index. Interestingly, however, the sign of the two volatility measures differ. An increase in stock market volatility results in higher disagreement, while the opposite is true for Treasury yield volatility. An increase in the slope of the term structure is associated with an increase in disagreement. Stock returns are negatively related to disagreement. Finally, an increase in unemployment is associated with a decline in disagreement.

5. Is disagreement priced?

5.1. Disagreement and expected returns

To examine whether disagreement about prepayment rates affects the expected returns of mortgage-backed securities, we use the standard approach of regressing ex
post realized returns on the ex ante measures of disagreement and other proxies for risk premia. If disagreement is priced in expected returns, then the disagreement index should have predictive power for the subsequent returns on mortgage backed securities even after controlling for the other ex ante risk premium proxies.

As discussed in Section 3, we make use of a proprietary data set provided to us by a major fixed-income asset management firm to construct a monthly return series on mortgage-backed securities. The lower panel of Table 3 provides summary statistics for the FNMA TBA returns.

Table 4 reports the results from the regression of the disagreement index on contemporaneous variables.

This table reports the results from the regression of the disagreement index on its first two lags and on the indicated contemporaneous financial and economic variables. Refinancing denotes the refinancing index reported by the Mortgage Bankers Association. Mortgage rate denotes the current coupon rate for Government National Mortgage Association (Ginnie Mae; GNMA) I mortgages as reported by Bloomberg. VIX denotes the Standard & Poor’s 500 volatility index as reported by Bloomberg. Treasury volatility denotes the Merrill Lynch Option Volatility Estimate (MOVE) Index of Treasury volatility as reported by Bloomberg. Slope is the difference between the constant maturity 10-year and two-year Treasury rates as reported by the Federal Reserve Board. Stock return denotes the monthly excess return on the Center for Research in Security Prices value-weighted index. Inflation is computed from the CPI-U index (Consumer Price Index for All Urban Consumers, nonseasonally adjusted) and other proxies for risk premia. If disagreement is significant at the 10% level.

Table 5 provides summary statistics for the FNMA TBA returns.

To explore the effects of disagreement on volatility and trading activity we use a simple vector autoregression model.
Table 5
Results from the regression of monthly mortgage returns on ex ante mortgage disagreement, financial, and economic variables

This table reports the results from the regression of the monthly mortgage return on the indicated ex ante variables, all of which are observed as of the end of the prior month. Riskless rate denotes the yield on one-month Treasury bills. Mortgage rate denotes the current coupon rate for Government National Mortgage Association (Ginnie Mae; GNMA) I mortgages as reported by Bloomberg. Mortgage duration is the Lehman/Barclays US MBS effective duration index for fixed rate mortgages reported by Bloomberg. Refinancing denotes the refinancing index reported by the Mortgage Bankers Association. Slope is the difference between the constant maturity ten-year and two-year Treasury rates as reported by the Federal Reserve Board. Corporate credit spread is the difference in the yield of Baa-rated bonds and the ten-year Treasury rate as reported by the Federal Reserve Board. Ten-year swap spread is the difference between ten-year swap rates and the ten-year constant maturity Treasury rate as reported by Bloomberg. Stock return denotes the monthly spread is the difference in the yield of Baa-rated bonds and the ten-year Treasury rate as reported by the Federal Reserve Board. Corporate credit spread is the difference in the yield of Baa-rated bonds and the ten-year Treasury rate as reported by the Federal Reserve Board. Ten-year swap spread is the difference between ten-year swap rates and the ten-year constant maturity Treasury rate as reported by Bloomberg. Stock return denotes the monthly excess return of the Center for Research in Security Prices value-weighted index. VIX denotes the Standard & Poor’s 500 volatility index as reported by Bloomberg. Treasury Volatility denotes the Merrill Lynch Option Volatility Estimate (MOVE) Index of Treasury volatility as reported by Bloomberg. Inflation is computed from the CPI-U index (Consumer Price Index for All Urban Consumers, nonseasonally adjusted) reported by the Bureau of Labor Statistics. Unemployment is the unemployment rate reported by the Bureau of Labor Statistics. The monthly sample period is April 1998 to January 2012. The reported t-statistics are based on the Newey and West estimate of the covariance matrix (with four lags).

(VAR) framework in which we include measures of all three of these variables. To measure mortgage return volatility, we use the daily return data described previously to calculate the standard deviation of returns for each month in the sample period. As the measure of trading volume, we use the total agency mortgage trading volume of primary government bond dealers reported by the Federal Reserve Bank of New York. This series is aggregated to the monthly level and includes both trading activity among primary government bond dealers and trading activity among customers of these bond dealers. An important advantage of this series is that it covers the trading activity of virtually every major dealer included in the PSA surveys. Summary statistics for the mortgage return volatility and trading volume measures are also presented in the lower panel of Table 3. We estimate the VAR using a specification that has three lags of the monthly change in the disagreement index, mortgage return volatility, and trading volume.

Table 6 reports the results from the estimation of the VAR system. Focusing first on the regression for disagreement, the table again shows that disagreement is strongly mean reverting because two of the three lagged changes in disagreement are negative and significant. Thus, an increase in disagreement this month tends to be followed by a decrease in disagreement in the next two months. No significant relation appears to exist between volatility and subsequent changes in disagreement. The results indicate that there is a relation between trading activity and subsequent changes in disagreement. In particular, changes in trading activity are significantly related to disagreement. The negative sign of the coefficient indicates that an increase in trading volume is associated with lower disagreement in the second subsequent month. This result is intuitive: As investors learn through trade, which gives them opportunities to update their beliefs about the drivers of asset value.

Turning next to the second regression for volatility, we also see that volatility is strongly mean reverting, with all three lagged values of changes in volatility significantly negative. This is not surprising given the well-known properties of return volatility. What is interesting, however, is that a strong positive relation exists between disagreement and subsequent volatility. In particular, the second lagged change in disagreement is positive and highly significant, indicating that an increase in disagreement tends to be followed by higher levels of mortgage return volatility. This effect can be viewed as providing support for Shalen (1993) and Zapatero (1998), who posit that a positive correlation exists between disagreement and price volatility. The results also show that increases in trading activity tend to be followed by higher levels of return volatility. All three lagged values of the change in trading volume are positive and significant.
Finally, turning to the third VAR equation in which changes in trading volume are the dependent variable, Table 6 shows that there is a strong relation between disagreement and trading activity. Both the first and second lagged changes in disagreement are significantly positively related to changes in trading volume. This effect can be viewed as providing support for Harris and Raviv (1993) and consistent with the empirical findings in Kandel and Pearson (1995). The results also show that increases in volatility are not significantly related to subsequent changes in trading volume, after controlling for disagreement. This provides evidence that uncertainty increases trading volume only when disagreement arises. Alternatively, disagreement is the mechanism by which uncertainty increases trading in the market. To our knowledge, this is the first paper to identify this relation. Finally, we again find that trading volume has a mean-reverting tendency as both the first and second lagged changes in trading volume are significant and negative in sign.

6. Concluding remarks

Understanding how information gets incorporated into asset prices could be one of the most fundamental issues in finance. This paper contributes by helping to show whether and how heterogeneous beliefs and differences in opinions are priced in the market. It also clarifies how investors take disagreement into consideration and what effect that has on the time series of asset prices.

Previous theoretical work tends to support a positive risk premium that is associated with disagreement. The equity risk premium as identified by Mehra and Prescott (1985) can be rationalized by introducing heterogeneous beliefs or differences of opinion (Varian, 1985, 1989; Abel, 1989). To our knowledge, this paper is the first academic study to show this fact empirically in a setting in which there are essentially no short-sale constraints or other trade frictions.

Disagreement is also associated with higher volatility and trading volume. This relation has been studied in theoretical work (Harris and Raviv, 1993; Shalen, 1993; Zapatero, 1998) and shown empirically by Kandel and Pearson (1995). In our paper, we find that disagreement is the primary channel through which uncertainty leads to higher trading volume. That is, volatility in and of itself does not lead to higher trading volume. Instead, it is only when there exists more disagreement that trading volume increases with uncertainty. This distinction has not been identified empirically in previous work.

Finally, disagreement could become incorporated into asset prices via two different mechanisms. As Banerjee (2011) highlights, investors can update their beliefs via a rational expectations mechanism or can agree to disagree, which results in persistent differences in opinion. By studying how return-volume characteristics vary with disagreement in the market, we find support for the rational expectations channel. We find that higher disagreement is associated with higher expected returns, higher subsequent return volatility, and higher trading volume. Especially given our finding that higher trading volume is associated with lower subsequent disagreement, rational investors are more likely to learn from prices and opinions in the market, updating their beliefs using Bayes’ rule.
